CONTENTS:

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah *in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.*

LETTERS TO THE EDITOR.

BAMBOO: ITS CULTIVATION FOR PAPER STOCK.

SIR,—My last letter to you of the 7th October, was based upon an extract from the Royal Botanical Garden Report 1877-78. Having the Report now before me *in extenso*, published in your October journal, I trust you will allow me space for a few additional remarks thereon, especially as, examined dispassionately, I submit that the conclusions drawn by Dr. King from his experiments "*that the proposed new industry does not present a hopeful financial aspect,*" are not only not justified, but must be regarded as being very far from conclusive, and that if a little more careful consideration had been given to the habit of the plant, a very different result would have been arrived at.

In February 1876, Dr. Brandis, the Inspector General of Forests, in India, issued a printed Memorandum directing attention to the main points to be determined by the experimental plantations of bamboo then ordered to be established by the Government of India. I assume therefore Dr. King's experiments had their initiative from this order. Why, then, he should not have at least tested the *various systems* of cutting or cropping the bamboo therein suggested, and not confined his experiments to the *one solitary system* he prophisied would not answer, unless it was to prove a "foregone conclusion," I must confess myself utterly unable to understand. I should have thought that on the contrary a scientific investigator would have tested every system that offered a prospect of a successful result.

I extract the following from Dr. Brandis' Memorandum above alluded to.—

"A method of treatment must, if possible, be discovered by which a "plantation, or natural forest of bamboo, may be made to yield a "succession of complete crops of young shoots throughout the year. "Our present experience is that a large proportion of *old stems* is "required in a clump to produce full-sized shoots. . . . . "Under ordinary circumstances, if bamboo clumps are cut over in the "forest, all mature stems being cut down at one time, the result is "a crop of slender stems, It requires no experiments to establish this "result . . . . Entire clumps of different species and of different ages "growing under the most favourable conditions should be operated on, "and these experiments should as much as possible be comparitive: "of a number of clumps of the same age and species, and growing "under the same conditions some should be thinned lightly, others "heavily, and the third group should be cut over completely, leaving "only a few old stems on the ground."

As you have published (in your March journal) Mr. Thomsons' letters to Sir Joseph Hooker, on the cropping and cultivation of bamboo, I beg to add the opinions of several other acknowledged scientific botanists bearing on these points at issue.

The most exhaustive work and generally accepted text book on the *subject is the Monograph by General Munro, C. B., published* in the transactions of the Linean Society, of which, like Dr. King, I have the honor of being a Fellow. General Munro did me the favor in September 1876, to reply to certain queries I had transmitted to him as follows:—

"I have never heard of the bamboo being cultivated for successive "cropping, but I see no reason why a regular systematic cropping could "not be carried out. *Bambusa Vulgaris* would in my opinion be the "best species to cultivate, as it grows very readily from cuttings; so does "*Dendrocalamus Giganteris*, which thrives remarkably well and grows fast "in Trinidad, W. I., and would I think produce the best fibre. *Bambusa* "*Tulda* would be a good species in India; *Dendrocalamus Strictus* also "grows fast and is easily propagated: the ordinary bamboo very rarely "seeds in the West Indies; I only saw it once in Jamaica, it is *always*

"increased by cuttings. I don't think these should be put in at a less "distance than five feet apart; a fair sized bamboo will produce from "10 to 20 shoots a year in moist countries. With reference to cutting "and cropping, I should think that 6 or 7 out of 10 shoots might be cut "yearly, without causing any serious harm to the parent stool; the "older stems might be cut down in their second year to serve as fuel: "I should think that the stools would continue to produce fresh stems "for about 30 years, about when the plants would be likely to come "into flower and then die."

The late Mr. Sulpiz Kurz, well known as an authority on bamboo, and whose most interesting papers thereon were published in the *Indian Forester*, in a long correspondence with me, replied to some queries as follows:—

"If all the shoots be cut down, the stock will be impoverished and ultimately die off, hence a certain percentage, say, one-fourth of the whole of "the stool, would have to be spared. The most common way of planting "bamboo by natives is by taking shoots, or the lower piece of the halm "with a part of the rhizome and plant during the rains, the intervals "between the cuttings being regulated by the size of the bamboo; 12 to "15 feet would be dense growth; for the larger kinds 80 feet and upwards, "which throw up from 15 to 20 shoots, while 8 to 10 feet is the "minimum for the smaller kinds above 30 feet; smaller kinds are not "recommendable."

Dr. Parish, a botanist well acquainted with Burmah and the Tenasserim Provinces, communicated with me as follows:—

"The shoots should not be all cut every year, for if this were done, the "root stock would die; only about half the clump should be cut yearly. "The bamboo once established as a strong root stock, you can go on "cutting annually; as to the calculation of 7,488 stems per acre (*vide* "my pamphlet p. 8) I should think that if only half were cut a much "greater number could be got off an acre."

Dr. Bethold Ribbenthrop, Conservator of Forests, Northern Division, British Burmah, to whom I had sent Mr. Thomson's letters requesting his opinion of the views as to cropping and cultivation, expressed therein, replied: "There is no doubt that in fire-protected plantations a much "larger crop can be obtained than in the open forest exposed to "constantly recurring jungle fires. The bamboo jungles near villages "on the Pegu choung, prove that constant cutting does not materially "affect the reproduction, and cutting them down within a couple of "feet from the ground, maintains a perfect unimpaired action of the "roots, as may be observed on the bamboo hedges in Rangoon. At the "same time I cannot agree with Mr. Thomson that a bamboo "plantation may be kept up indefinitely in regard to time, at least not "without re-stocking: this has been the case with the artificial plantations of *Dendrocalamus Brandisii* here in Burmah, original stocks of "which die after about 60 to 70 years, others would doubtless be "shorter lived.

"The *Dendrocalamus Brandisii* plantations in Burmah, are kept up "by inter-planting with new stocks. Mr. Thomson's system is "doubtless the correct one; to grow bamboos like sugar-cane, and to "replant after cutting the crop seems to me impracticable, the "maturation of small bamboos taking at least 2 years, that of the "larger kinds 5, 6 or 10 years."

In another letter Dr. Ribbenthrop addressed me, he said: "All my "observations regarding the growth of many species of bamboo tend "to prove that you are perfectly correct in your views, and that by "artificially irrigated plantations we can force the productive power "of bamboo stocks to a very great extent, on the Pegu choung and "the Beningdat, the most luxurious growth is found close to the water "courses, where they are most severely cut for the bamboo trade, "the banks of the Attaran river are for upwards of 50 miles fringed "by a broad belt of large dense growing, but for general purposes, "useless bamboo."

There are yet other points in Dr. King's Report I should like to discuss, but having already occupied so much space, I must leave these for another letter.

Claxheugh, Sunderland, 30th October 1878. THOS. ROUTLEDGE.

BAMBOO PAPER.

SIR,—This is largely manufactured in China. Fortune, at page 270 of his *Two Visits to the Tea Countries of China*, says:—

"While these thoughts were passing through my mind, my people arrived, and, getting into my chair, I proceeded across the valley. About a mile below the temple (of Shante-Maon) I observed a a manufactory for making paper out of the bamboo. Large stone tanks were constructed in the fields for the purpose of steeping the bamboo stems. They appeared to be steeped for a length of time in some solution of lime. They were then taken out and beaten upon stones until they became quite soft, or until all flinty matter which abounds in their stems was removed."

This note occurs on his journey from the Woo-e-shan district to Shanghai, *via* Ching-hoo.

I send this to you to suggest the advisability of opening communication with the Anglo-Chinese authorities, for information regarding the cultivation of the bamboo and its manufacture into paper.

G. P. P.

NEGLECTED FORESTS.

SIR,—As sâl wood is now selling at such high prices, and as Government is preserving forests where practicable, it may not be out of place for me to call the attention of the proper authorities to the fact that there exist in North Bhaugulpore 70,000 to 80,000 or more biggahs of sâl jungle, which is being annually cut for firewood and stolen by the jungle residents for converting into charcoal and ploughing implements. The zemindars, who are a needy set, frequently sell it at Rs. 10 to Rs. 15 per biggah, and do not seem to appreciate the value of their possessions. The trees vary from 10 to 40 feet in height, and if the brushwood were cut down and proper conservative measures adopted, it can be well imagined how the value of the forests would increase. Under the present system of annual demolition it seems probable that 30 years will see the last of these promising forests.

PEACOCK.

MUMMY WHEAT.

SIR,—I had a discussion with a friend who maintains that there is a species of wheat called "mummy wheat" grown extensively in England, and the seed of which was originally found in the swathings of mummies in Egypt. I said that this was a popular delusion, that it was impossible for any seed to retain its germinating power for 3,000 years or more, and that I had the authority of Lindley in his work on horticulture for my belief. My friend does not care for Lindley. He would be satisfied by your decision in the matter, whether wheat or any other seed could retain its germinating power for so long.

MUMMY WHEAT.

NOTE.—The wheat referred to is the *Triticum compositum* or many-spiked wheat, a distinct species, coming from Egypt and cultivated in a few places in England, but not extensively. Some wheat that was obtained from the swathings of mummies over 2,000 years old, was found to germinate, and yielded plants of identically the same species. Hence the name "Mummy Wheat." But it is by no means proved that this species has been extinct in Egypt and revived only by seed found as mentioned above. Still the fact in which our correspondent would seem to be specially interested, is beyond doubt, *viz.*, that corn has in modern times been raised from the seed found in a mummy case.—ED., *I. A.*

THE SAME.

SIR.—Your note to my letter of the 3rd instant does not clear up the point in dispute between my friend and myself; in fact the only additional information your note gives is, that the wheat called mummy wheat is the *Triticum compositum*, and that it is not grown *extensively* in England. You do not decide the main point, whether the seed obtained from the swathings of mummies is the identical seed put in there when the mummies were embalmed. Supposing any seed were really put in with them, my friend and myself are quite agreed on all points except as to the identity of the seed. I have the authority of Lindley for my belief that it is not the same seed that was put along with the mummies. Will you kindly tell us if botanists believe that the seed from the mummies, from which the *Triticum compositum* has been propagated in England, is of the same age as the mummies?

MUMMY WHEAT.

NOTE.—There is no reason to doubt that the wheat found in the swathings of Egyptian mummies is of the same age as the mummies themselves.—ED., *I. A.*

DEGREES IN AGRICULTURE.

SIR,—We have heard good deal lately of the Governor of Bombay's wish and intention to develop the C. E. College at Poonah into a College of General Science and Agriculture; on which subject, Mr. Robertson, the Head of the Agricultural Department of this Presidency, lately proceeded to Bombay in order to consult and advise Sir R. Temple. You have often in your columns urged the advisability of the local University instituting something of a similar nature, and have pointed out how much more beneficial it would be to the country at large, if we turned out a number of Bachelors in Husbandry, instead of B. A's. In the Civil Engineering College at Chepauk, and the Agricultural College at Sydapet, two excellent institutions exist, which, if combined, would

be able to inaugurate such a course of study, as would enable a thorough training to be given in Civil Engineering, General Science, and Agriculture, and thus enable the University to grant degrees in Science, and Husbandry, as well as in Civil Engineering, as they do at present. That the Civil Engineering College would benefit by removal from Chepauk to Sydapet, there can be little doubt, and much greater opportunities must exist at the latter place than at the former, for teaching the practical portion of the Civil Engineer's profession. The building at Chepauk, now occupied by the C. E. College, would afford room for some of the offices at present overburdening the Fort.

The University, however, would require to modify its Faculty of Civil Engineering, in order to include General Science, and Agriculture. The future constitution of the Faculty might be something as follows :—

Chief Engineer.
Chief Engineer for Irrigation.
Consulting Architect.
Principal of the C. E. College.
The Head of the Agricultural Department.
One of the Professors of the Agricultural College, either Chemistry, Natural History, or Veterinary Medicine.
A Second Scientific Agriculturist.
The Government Astronomer.
The Chemical Examiner.
The Director of Public Instruction.
The Conservator of Forests.

Such a body would be fairly representative of the three subjects with which it would have to deal ; its only fault, perhaps, would be in being too weakly represented in the agricultural division ; agriculture being it is now acknowledged of at least as great importance in this country as Civil Engineering.

If Government would insist that all its subordinate revenue officials should obtain a degree in husbandry, the advantage to the country would be enormous ; and with a view to such a contingency arising the University should not be unprepared.

SUGGESTION.

December 13.

FERN-CULTURE.

To the Editor of the Madras Mail.

SIR,—Will some one of the many readers of the *Mail*, versed in plants, inform me how the fern best known as the *Cycas* and *Zamia* may be re-produced. The trunk is mostly under-ground, and is about two feet long by two feet in circumference. The leaf is about four or five feet long with small narrow leaves on each side of a long stem. I have made many attempts at transplanting slips and roots, but all have failed. As many friends are anxious to have it, I would feel obliged if some one will favor me with the information.

FERN.

Nellore, December 4.

THE SAME.

To the Editor of the Madras Mail.

SIR,—In reply to your correspondent " Fern " I beg to state that *Cycas* and *Zamia* are not ferns, but they comprise a genus of plants allied to palms and ferns. They are produced readily from seed ; but are slow growers. They abound in the Malabar district. Many of these plants may be seen in the gardens on the side of the high road leading from Beypur to Calicut. They are also met with in the Salem district ; some two or three years ago, I collected a lot of seed for distribution at the foot of some hills about five miles from Sunkerydroog on the high road to Trichengode ; as also from some plants found growing on" Morison's Farm " at Palmanair.

The male and female plants are distinct, the seeds form nuts about the size of a common hen's egg, but quite round, hanging down from the plant from a spadix resembling somewhat a miniature form of the fruit of a cocoanut tree. I have two plants now from seeds put down nearly three years ago, and they are only about a foot in height and have two fronds each. They may be grown from cuttings of the fronds. Occasionally some plants throw out suckers, these when separated will thrive. I should say the nuts or seeds are the best means of propagating the plants ; they are eaten by the poor, ground into a flour and cooked in a sort of kunjee. The cycads with age, attain from five to eight feet in height, when much of their beauty is lost by their lanky stems.

JOHN SHORTT.

12th December, 1878.

EUCALYPTI IN INDIA.

SIR,—The gum trees of Australia have in some localities been introduced into this country for above a decade. I write to inquire, whether they have been known to bear fertile fruit anywhere as yet? There is a plantation near the bunds of the Chenab, in which there are at least fifty trees of the *Eucalyptus-resinifera* or *E. pepera* planted from seed imported by a Railway Engineer ; they are about six years old, have grown very rapidly, and they have borne carpels, but as yet do not seem to be fecund, they probably are the first fruits of trees which are not yet adolescent. However some information on this interesting family of trees would be useful. Much ignorance of them prevails ; for instance a friend used to go about splitting the bark up with a stock-knife to prevent them from being hide-bound, as he termed it. The trees on the bank of the Chenab appear to have an healthy influence on the malarious character of their immediate locality ; the pleasant odour from them can be snuffed in the air. It may be as well to point out, that Lahore has recently become very unhealthy owing to the extensive plantations of " sheshum " trees. The forest department ought to know, that these are an unwholesome kind of tree to plant in marshy ground, the stench from their leaves rotting is very offensive. I would suggest that these plantations be cleared away, and the *Eucalyptus* planted, which thrive amazingly in such moist soils and are so salutary.

W. J. B.

AGRICULTURE IN EUROPE.

(FROM OUR CORRESPONDENT.)

PARIS, NOVEMBER 7.

IT is up-hill work to be an innovator. M. Faucon for several years has saved his vineyard from the phylloxera by inundating the vines in autumn for two months, and liberally manuring them in spring. People disbelieve him, although he invites the incredulous to come and see. M. Goffart, of Burtin, is another case in point ; he has introduced the plan of feeding and fattening stock on chopped green forage, preserved in trenches, during every season of the year—winter and spring especially ; he also is despised and rejected. He lately invited the agriculturists from all parts of the world, brought together by the Exhibition, to witness his system at work. Some 100 cosmopolitans accepted his princely hospitality, extending to even placing a special train at their disposal. The carts laden with the freshly cut Nicaragua maize-stalks of giant proportions, discharge their loads ; the stuff is raised by machinery, driven by a turbine which also works a saw-mill, and passing from the feeding board to the knives, it is chopped into rings one-third of an inch thick ; thus shaved the stuff is again lifted, and slides down into the trench, where a man and woman spread and tread it ; when full, the trench is covered with boards, on which large stones are piled at the rate of 8 cwts., to the square yard. In this condition the forage will keep admirably, and without fermentation, till required for use ; it will remain for months without becoming heated or deteriorated. The trenches are 40 feet long, by 16 wide in cement, and the roof is 6 feet above the well, to allow room for working the planks and the stones. Beside the building is the old trench, sunk in the soil, and filled with cut green rye, since May last perfectly preserved. The trenches, or reservoirs, are elliptical, because corners interfere with safe pressing down. M. Goffart has 68 head of cattle, and has sufficient fodder thus conserved, to feed or fatten 90 more. The stuff when taken from the pit, is at once served to the animals, who devour it with a gusto.

In the south-west of France, cotton-seed cake is entering largely into the dietary of farm stock ; the preference is given to that prepared from Egyptian seeds, as it contains fewer filaments of cotton, is more nutritive, and less liable to become musty. It is in Marseilles this kind of cake is obtained, where each manufacturer is obliged to stamp on each cake the trade mark of his establishment—a guard against fraud. Cattle and sheep eat the cotton-cake with avidity when simply crushed, and without any mixture ; it takes the place of meal and potatoes, when joined to beet, for the feeding of pigs, and horses accept it with their oats, chopped hay, or bruised maize. It resists best humidity, as compared with linseed, colza, or hemp cakes, and is cheaper—6 francs per 112 lbs., taken at the factory. Cattle may be given 6 lbs. daily of cotton-cake, pigs 2, sheep ¼ of a lb. and horses somewhat less. The chief objection against hemp-cake lies in the difficulty of preserving it in large quantities for any length of time ; it is best when obtained daily from the mill ; it is nutritive and cheap, though some allege that it is heating, especially for young animals, like colza.

There is but one regret to register in connection with the agricultural section of the Exhibition, *viz.*, that all the implements and machinery, instead of being scattered over the palace in annexes, had not been concentrated in a single building. Class 51 comprised agricultural implements, besides processes employed in the cultivation of fields. There were 496 exhibitors; France had 207; England and her colonies 83; United States 41; Belgium 18; and Russia 24. There were shown a total of 248 ploughs, 137 threshing machines, 28 scarifiers, 62 mowers, simple and combined; 58 reapers, 104 sowers, and 20 machines for tilling land by steam. The jury consisted of 13 members; 5 for France, 2 for England, 1 for the United States, and the remainder for other nations. The jury devoted 86 days, of three hours each, to the actual examination of the exhibits, and 12 more to deliberations. Eight nations, though competitors, obtained no prizes. China, Japan, Central and South America, Portugal &c. There were awarded, 6 Diplomas of Honor, 32 gold medals, 79 silver, and 89 bronze ditto, *plus* 78 honorable mentions, or a total of 284 recompenses, being at the rate of 58 per cent. of winners, on the entries. In the Order of Merit, based on the honors won, for the number of exhibitors from each nation, the following is the position, taking 100 as a standard: the United States score 88, Belgium 82, Austria 77, England and Hungary 72, Denmark, Norway, and Russia 67, France and Holland 50. But of the 32 gold medals, England has obtained 10, the United States 4, and France 15. The threshing machines shown by England, France, the United States and Russia, were very superior,—the American ploughs were magnificent, and were distinguished by careful workmanship, solidity and form, united to cheapness; in addition many of the implements were very ingenious. The general display of reapers and mowers was most excellent, and the day cannot be distant when the "perfect harvester" must appear.

What may be called the "Dairy Congress" held at the Trocadero was interesting, and treated chiefly on the preparation of butter; the feeling seemed to incline towards the Scandanavian plan of churning at low temperatures, which economises time, ensures the butter keeping better, and secures its aroma; if the process has failed, such is the consequence of not following correctly the system. An observation was made, that much of the difference existing as to the richness of milk in fatty matters resulted from bad instruments made to measure the quality and that lactometers were very defective. A prize is to be offered to the inventor of an instrument for testing the presence of margarine, and other matters employed for adulterating butter, and which it seems enter largely into the butters exported or sold in large towns. Margarine sells for one-third the price of average butter, hence the profits must be enormous. In Paris, there are establishments specially devoted to the sale of margarine, and have the air of model dairies, or of such as Marie Antoinette conducted, personally, at the Trianon.

A farmer has noted that when he covered a strip of loamy soil with a slight layer of river sand, the soil beneath was markedly fresh and moist, and patronised by worms, while at the sides, the soil uncovered was nearly as hard as a rock. The reason is simply owing to the sand acting as a screen, preventing the sun's rays from evaporating the moisture, the surface being thus kept humid, no water ascends from the subsoil by means of capillary action. The same effect is produced, and often beneficially, despite the loss in ammonia, when farm-yard manure is applied on the surface of the soil and never turned in.

There are a few annexes of the Exhibition devoted to commercial manures—to what may be called the scientific results of agriculture. There are companies and private fabricants who have seemingly an endless collection of fertilisers. It is the practical triumph of chemistry which, discovering the secrets, more or less complete, of the fecundity of soils and the necessities of vegetation, has acted accordingly. Science, as Liebig has well said, either approves or invalidates the conclusions of practice. There are exhibited even special fertilisers for kitchen and flower gardens. What progress since the seventeenth century for France, when a royal decree directed that the mud of Paris, its night soil, and the offal of the slaughter houses, were not to be employed as manures till they had rested three years in a common pit! It was Lavoisier who may be said to have found agricultural chemistry, or what is summarily known now as "agronomical stations," where the laboratory is in connection with field experiments. The Revolution swept away Lavoisier and his laboratory. Boursingault took up his idea, and effected some valuable experiments, though in a private capacity; Germany followed up his discoveries, and at once took the lead in establishing agronomical stations, above all, controlling the sales of commercial manures, as the chemist has the right to enter the factory when he pleases, and select samples for analysis, nay more, the farmer even after purchasing has the right to select his sample and have it gratituously analysed. France quickly followed in the wake of Germany, and has now no less than 80 "stations," the chief being at noted scientists; he executes analyses for the universe at large. The station at Anas is famed for its study of the cultivation of beet, in connection with the production of sugar and of alcohol. It is at this farm that M. Pagnoul has been able to formulate laws as to the action of nitrates on beet. The root is best suited for the sugar fabricant when the plant grows rapidly in the first three months of its vegetation: the nitrates then pass into the leaves and stimulate development, now, if the latter takes placed markedly only in a warm and humid autumn, fresh rootlets are thrown out, the nitrates and ammoniacal sulphates, instead of being gradually worked up, rapidly concentrate in the bulb, and produce disastrous results on the yield of sugar.

The distilling apparatus of M. Champonnois has received a grand medal, and the inventor himself has been decorated. It is suited to ordinary farms, and enables the sugar of the beet to be extracted and converted into alcohol, the residual matters being left for feeding purposes. The alcohol is exported, and the pulp remains for conversion into meat, milk, and manure.

The yield of beet in France this year, and the same remark applies to Germany, is now known to be inferior to that of 1877. Germany had 260 sugar factories in full work during September. The selling of the beet according to the relative density of the juice is making way in France, and promises to become general; it will protect both the farmer and the manufacturer, and will above all, give the death-blow of the employment of nitrates late in the season.

The Indian Agriculturist.

CALCUTTA, JANUARY 1, 1879.

TEA PRODUCTION IN ASIA.

It is scarcely more than a decade since China had the monopoly of providing the world with the "cup that cheers but not inebriates"; the change that has since taken place with regard to the sources from which the world now draws its supply of this important article of commerce, has been so great, and has been so vital in developing the resources of India, that a review of the present state of tea production in Asia, will have a more than passing interest to our readers. China has lost its monopoly and India and Japan have now entered into the field as considerable factors, increasing the world's supply of tea. Their teas are now influencing greatly the European and American tea marts, and it seems as if the China tea trade had reached its maximum in 1875, and is beginning to give way gradually to its younger and more vigorous rivals. As in India so in Japan, tea is now one of the staple products, and as the area of tea cultivation in those two countries is yearly increasing, the interests vested in the China tea trade are seriously threatened.

The official returns show the export of China tea from the treaty ports to have been

Total ...	1,762,813	36,647,926

During the last six years the exports from China amounted in quantity and value to

				£	
1871 ...	203·0	million lbs.,	value	12	millions.
1872 ...	214·4	"	"	13½	"
1873 ...	195·6	"	"	2	"
1874 ..	210·0	"	"	11¼	"
1875 ...	220·0	"	"	11 1/5	"
1876 ...	213·3	"	"	11	"

To this must be added the exports by caravans to Eastern Europe, to Siberia and to the districts north of the Himalayas, which amounted in 1876 to 152,000 piculs. The yearly home consumption of tea in China has been estimated at two-thirds of the total production, the exports at one-third, so that China must have produced in 1876 more than 600 million lbs. of tea.

Europe absorbs now nearly the whole of the tea exported from China, Chinese tea having, in the American markets, been almost entirely superseded by Japanese tea. The trade is chiefly in the hands of English merchants and is likely to remain so, as the United Kingdom alone consumes more than half the exports—during the year 1876, 125 million lbs. We stated that the year 1875 has probably seen the height of the Chinese tea trade. In 1876, for the first time in the annals of the trade, did the quantity of tea exported from China remain stationary, though the consumption, in Great Britain alone, increased by 5,000,000lbs., the excess being entirely drawn from India. During 1877-78 the exports from China to Great Britain and the Continent were twelve million lbs. less than during 1876-77. Indian and Japanese tea, the former in England, the latter in America, are coming into greater favour day by day among the consuming classes and it is therefore only reasonable to expect a considerable decline in the Chinese tea trade, and a corresponding increase of that of its competitors. Ceylon is also entering the list, and will, in less than a decade, figure probably as a not unimportant exporter of high class teas, large areas of available and suitable land being now taken up in that island for its cultivation. The inferiority of the bulk of Chinese teas is of course the chief reason of their being supplanted by the superior Indian and Japanese teas, whose superiority lies not so much in their innate qualities, as in the more skilful manufacture. The great competition among European merchants in China has a great deal to do with this deterioration. Every firm endeavours to obtain the first shipment and pressure is brought to bear upon middlemen and by them upon the growers, who pluck the leaf often before it is fit for plucking, and all the ensuing processes of manufacture are conducted with such carelessness, that it is surprising the result is not worse. The firing of the leaf, for instance, takes place several days, generally one or two weeks, and often a month or so, after the leaf is plucked; the merest tyro in tea manufacture knows how necessary it is, to fire the leaf as soon as possible after the plucking. Consul Medhurst's report on the Chinese tea trade deals with this subject in detail, and he is of opinion that nothing but the introduction of European capital and enterprise can save the tea trade from decay.

We have on more than one occasion drawn attention to the extraordinary growth of the Indian tea industry, which we may say, has surprised the whole world, and is a striking and creditable example of what Anglo-Saxon capital and energy is capable of. In 1851 the exports of Indian tea from Calcutta, amounted to 262,839lbs., in 1877 we exported 31,784,000lbs.

The area of cultivation in Assam, Bengal, North-West Provinces and Madras is still (though now more gradually) increasing, and the quality of tea, though it lost considerably in repute during the last year, has during the present year fully recovered its high character. Fifteen years ago tea cultivation in India was looked upon as a doubtful experiment; it is now an important industry, in which vast capital and European energy is engaged. The following statistics show what enormous strides the industry has made.

Exports of Indian Tea to England.

During the year 1860	... ...	1·4 million lbs.
" 1865	... ...	2·7 "
" 1870	... ...	13·2 "
" 1871	... ...	16·4 "
" 1872	... ...	17·9 "
" 1873	... ...	19·7 "
" 1874	... ...	23·3 "
" 1875	... ...	26 1 "
" 1876	... ...	29·4 "
" 1877	... ...	31·7 "

The consumption of Indian tea in Great Britain compares with that of Chinese tea in the ratio of the relative quantity imported. The ratio of the imports of Indian tea to that of Chinese tea stands :—

In	1872	as 1	to	9·7
"	1873	" 1	"	7·4
"	1874	" 1	"	7·5
"	1875	" 1	"	6·7
"	1876	" 1	"	5·6
"	1877	" 1	"	5·5

The tea industry in Japan has likewise increased in importance, though its growth has been slow, compared to the Indian tea industry. After a standstill during the seasons 1871-73, followed a rapid extension during the season 1873-74 until 1875-76. Previous to 1873, the total exports from Japan amounted on an average to 12·5 million lbs., rising even under the most favourable circumstances never higher than 18 millions, while the quantity manufactured for export during the ensuing years was :—

Season 1873-74...	... ...	19,816,000 lbs.
" 1874-75...	... ...	24,976,000 "
" 1875-76...	... ...	29,326,000 "
" 1876-77...	... ...	24,722,000 "

The demand for this tea in the American markets, the improvement of communications in the interior of Japan, the development of its export trade and the opening of its chief ports, have done much to develop this industry in Japan. There was a serious falling off in quality in 1876-77, which we noticed at the time, said to be due chiefly to the carelessness of the growers and manufacturers; the losses which were incurred during that season, owing to the great fall in prices must have been a severe lesson, and we hear the tea of season 1877-78 better spoken of. The actual exports from the chief ports in Japan were :—

	1874-75	1875-76	1876-77.
From Yokahama ...	16,547,375	18,885,743	16,177,272 lbs.
" Hiogo ...	4,292,159	6,080,036	6,520,527 "
" Nagasake ...	1,043,704	1,060,000	987,817 "
Total ...	21,883,238	26,027,779	23,685,616

Nearly the whole of this went to the American markets, only small parcels aggregating 400,000 to 500,000lbs. being shipped to London. The consumption of tea in the island is said to amount to nearly 4 million lbs., which has

to be added to the export in order to get the total production of Japan.

China, India and Japan are the principal tea producing countries in Asia, though Ceylon and Java are also likely to become of importance as such during the next decade, about 3,000 acres being now under tea in Ceylon and this area is being rapidly added to. From Java the exports of tea were in 1873 valued at 2,400,000 florins, in 1874 at 2,700,000 florins,—quantity not ascertainable.

The total production of tea in Asia for export, may therefore be estimated as amounting now to 280 million lbs.

ADVANTAGES OF REDUCED ACREAGE.

ON page 428 of this year's *Agriculturist*, Colonel Vertue makes a suggestion which seems to us worthy of being followed up. Colonel Vertue advocates that ryots should be encouraged to plant a smaller area, but to spend as much labour and manure on that smaller area as they did on the larger. This seems to us a valuable and practicable suggestion and is within the reach of all.

Let us suppose a ryot, who usually cultivates 50 acres and who spends Rs. 24 per acre, this represents Rs. 1,200, including of course value of his own and his bullocks' labour, well let him spend this Rs. 1,200 still, but let him only cultivate 30 acres. There will be a saving in seed, namely the seed that would have been used on the abandoned 20 acres. The 20 acres not being required for cultivation, will be left fallow, and may be profitably used for cattle grazing purposes, grazing land being much wanted, as the breed of cattle is rapidly deteriorating all over the land, on account of, among other causes, want of proper grazing. There will be likewise a saving in irrigating expenses and in fencing and in having to watch a smaller extent of country as crops ripen. Each acre will under this system cost, say Rs. 40 to cultivate instead of Rs. 24, the difference Rs. 16 being expended on the land in deeper cultivation and in manuring, and doubtless the result will be a larger amount of grain from the 30 acres, than was formerly obtained from the 50 acres, with less trouble in many ways.

The only difficulties in the way of this reform are prejudice and indifference; naturally the ryot prefers to follow in his forefather's foot steps, but this will be the only real difficulty. He is stubborn, but somehow he looks earnestly to his own interest; if we can only penetrate his prejudice and shew him where that interest lies. The question is then, how is he to be led to see, that this change will be for his advantage, without at the same time interfering too much with his time honored habits—call them prejudices if you will. Model farms will not do it, for they have proved to be an unsuitable medium of instructing the ryot. Their career has not been of such a nature as to induce him to follow the bent of their teaching or rather leading. True, they have raised larger crops as one result of their experiments, and the crops produced have been superior in point of grain and straw, but the cost has been out of all proportion to the result. It must be acknowledged that the ryots look upon these farms as decided failures, and we confess they are amply justified in many instances, in so regarding them.

But Government has otherwise ample means at its disposal to try this experiment. The estates under the Court of Wards will be found most suitable for this purpose. Let the manager of these estates select four intelligent ryots—and ask them to try the experiment on small plots of about four acres each, at the same time guaranteeing them against actual loss. This would not lead to an extensive risk on the part of estate, and would give the experimentalists confidence. Steps would have to be taken of course to see that extra labour and manure were actually expended, and we feel convinced that the second year would shew highly satisfactory results. Granting this the ryot might then be left to himself to follow it up, and this he would do, as self-interest is the spur that will push him on if anything will.

AGRICULTURAL EDUCATION IN THE BOMBAY PRESIDENCY.

ADVERTING, in our issue of October 1877, to the great success that has attended the establishment of agricultural schools and colleges in Europe and America, and the great national benefit that is now derived from the spread of agricultural education in these countries, we urged Government to initiate throughout the country a similar movement, adapted to the peculiar circumstances in which the Indian agriculturist is situated. We wanted to see, we said on that occasion, agricultural colleges, one in each Presidency, agricultural schools in the districts; we desired, we said, the science and practice of modern agriculture taught, not only learnedly in Colleges and High Schools, but also modestly in every village.

We rejoice therefore, to be able to record to-day the resolution of the Bombay Government, published elsewhere, to make a beginning at once in the direction we pointed out. Often as the claims of Indian agriculture for improvement have been acknowledged by the Government of India, they have never as yet been met by such a practical scheme as that which has been matured by His Excellency Sir Richard Temple, and if this scheme is carried out in the form proposed in the resolution—and in that case we are certain of its success and of the great benefit it will confer upon the agricultural classes—then Sir Richard Temple will have cause to be proud of having been the mover in establishing a simple, and yet complete system of agricultural education suited to our peculiar circumstances. There is no greater benefit that can be conferred upon the vast rural population of India than an improved system of agriculture; and there are no better means by which this great goal can sooner be reached than a system of agricultural education that reaches down to the village school. Sir Richard Temple's proposals embrace the establishment of an Agricultural College in connection with the Civil Engineering College at Poonawith the ultimate view of establishing another College in Guzerat, the garden of Western India. A study of three years will prepare the student to go up to the Bombay University for an Agricultural Degree, and what is most important, native appointments in the Revenue Departments, as Mamlatdars, Mahalkaries Karkoons, &c., will preferably be given to those who have thus graduated, if it cannot be arranged that all these officials shall in future be drawn from graduates in agriculture.

To feed the College class, six agricultural classes will be established in connection with High Schools; three of these are to be in Guzerat, one in Khandeish and the others in the Deccan. The teachers are to be drawn from the agricultural students who will pass successfully and will have completed a three years' curriculum, in June next, at the agricultural institution at Sydapet. The Poona College is to supply in future the teachers for the High Schools, and when a sufficient number is available, they will be utilised as teachers of elementary agriculture in vernacular and village schools. It will be seen therefore that the scheme is well matured and complete and the only doubt

left in our mind is, whether it can be put in force at no greater yearly expenditure than £1,500, a ridiculously small sum surely for such an important branch of education. However we wish Sir Richard Temple every success, and thank him for having moved out of the accustomed groove. The resolution, if carried into effect with the same spirit that penned it, will mark an era in the history of our administration of India.

EDITORIAL NOTES.

As an instance of what improved cultivation can do, we give prominence to the following results obtained in the district of Dehra Doon, where tea has not yet had fair play, except in very rare instances, we may say, in one instance only—and that case shews results that may fairly be considered most satisfactory and conclusive. The general rule of working there has been and still is, to have the cultivation carried on at the least possible cost. One would almost think the object in view was not to develop the plant, but simply to prevent the land from lapsing back to primitive jungle. But one company has gone out of the beaten track, and has for some years been encouraging a liberal expenditure on its gardens, with the result of obtaining 440lbs. of Tea per acre in 1877, and over 500lbs. during the season just closed, whereas the run of outturn in the Doon is from 150lbs. to 300lbs, 240lbs. or 3 maunds per acre being a liberal average. Allowing the excess yield in this case to have been 240lbs. per acre, this would represent an additional return of Rs. 150 per acre, which pays thrice over for the extra cultivation.

We regret to hear that it has been decided to abolish the Bangalore Experimental Farm. This move appears to be the result of an unreasoning fit of economy. Besides the Superintendent himself, there are only a few coolies, and several convicts on the establishment, yet, in spite of all these drawbacks and difficulties, Mr. Harman has rendered the Farm quite a success, as the last annual report shews. Now, after the lapse of fully three years, and an expenditure of Rs. 80,000 upon it, the Farm is to be abolished. It is stated on good authority that the abandonment of agricultural reform operations did not emanate from Mr. Gordon, the Chief Commissioner. His proposal was to abandon the Bangalore Farm, and start a more central one in Mysore. The Viceroy and his advisers, however, do not seem to believe in improvement in agriculture as a preventive of Indian famines. So the Farm is doomed. There is yet, possibly, some hope that the ryots' thirst for agricultural knowledge will be satisfied. Mr. Caird, C. B., of the Famine Commission, is now on a tour through the northern districts of India, and may probably visit Madras and Mysore. It is believed that Mr. Caird is strongly in support of agricultural reform as a means of preventing the recurrence of famines.

A contemporary tells us that the Chemical Laboratory attached to the Agricultural College at Sydapet, is now completed. It is a substantial building, including verandah, about 80 feet by 40, and about 20 feet in height. It is well ventilated and affords accommodation for thirty students working at one time, and private accommodation for the chemical lecturer is being fitted up. The chemical apparatus, fittings, &c., have just been received from the Secretary of State for India. The College building, which has long been most urgently needed, has, at length, been sanctioned for immediate commencement. It is to be a two-storied building with a tower at one end. The ground floor, however, is only to be taken in hand at present. This consists of a lecture theatre 30 feet wide and 50 feet long, with terraced seating; a lecture room, 25 feet wide and 40 feet long; and three class rooms, each 20 feet by 25 feet. The rooms will be lofty and well ventilated. The whole of the building is to be surrounded by a wide verandah. The upper floor will provide similar accommodation to the ground floor. There are now two classes at work in the College, each consisting of about thirty members, or about sixty in all. In addition, a course of lectures on Agriculture is being delivered by Mr. Benson at the Normal School to a class of about twenty-five students. So Madras has a good start ahead of Bombay, and should make strenuous efforts to maintain her supremacy in this respect.

An Agricultural Exhibition is to be held at Burdwan on the 27th of January next, and four following days; and to judge from the handsome prizes offered and the liberal treatment which the committee extend to exhibitors, the Exhibition will deserve, if it does not command, success. The prizes are divided into three classes—those for residents of the Burdwan district, those for residents in the Burdwan division, and those for all-comers. Department I includes cattle, horses, and donkeys, sheep and goats, poultry, wild animals, and dairy produce. Department II includes implements. Department III agricultural produce and raw materials; and Department IV brass and kansa work. In the first, prizes will be given amounting to Rs. 1,100, in the second to Rs. 1,000, in the third to Rs. 1,000, and in the fourth to Rs. 1,000. But in addition to the money prizes, every winner of a first prize will receive a silver medal, and instead of money, winners of more than Rs. 20 in value can have a cup, with a suitable inscription on it, should they prefer it. All necessary arrangements for the convenience of exhibitors will be made by the committee, if communicated with, and all intending exhibitors should communicate with the Secretaries before the 5th of January. The Exhibition ought to be a success.

We have received the prospectus of a new banking institution to be called the "Rohilkund and Kumaon Bank" which it is intended to start early this year, with a capital of Rs. 1,00,000 with power to increase. The head office is to be at Naini Tal or Bareilly, The Bank has good prospects we think, and from our knowledge of Mr. Lancaster in particular, we can honestly commend the project to the public. One must have been in the North-West, to understand how great a public convenience these small local Banks really are. The great crying want of the Mofussil moreover, is capital to set the springs of industry in motion. A net-work of such banks spread all over the Mofussil, might we think if wisely assisted by the State, be made an important step towards improving the agriculture of the people, by assisting them with small loans after the fashion of the old Scotch banks. The circumstances of the country demand original statesmanship, but where to look for it, we do not know. The finance department and its Minister are absorbed with the task of making both ends meet, and with the mere routine of book-keeping estimates, and audits. Never surely was there a time at which, nor a people for which, so much required to be done by private enterprise to assist the State. It would be true wisdom we think, and statesmanship for the Government itself to show an interest in these small local banks, assisting them, if necessary, with the means to make the *taccavee* advances to the cultivators that were so common under native rule.

It is most difficult for the State to make those advances directly, but we cannot but think that wherever one of these small local banks exists, it should be made a sort of centre, or heart, for circulating money amongst the cultivators, and reducing the rates of interest that now strangle the life out of the people. We wish twenty such banks were starting instead of one *only*; but then we should look to make something more of them, than a mere convenience to *English residents in the Mofussil, and the tea-planters* of the Himalayan valleys. General Strachey will tell us, and truthfully, that *he* has no time to attend to such suggestions. It is none the less our duty and vocation to make them. We have made a good many suggestions at intervals that time has shewn to be valuable, and we cast this "bread upon the waters" once more to be found perhaps after many days.

Dr. J. König, has recently published the results of his investigation into the composition of ground rice-husks, which appear to have been strongly recommended in some quarters as a valuable food for cattle. He finds the meal to contain 8·91 per cent. of water, 2·75 of protein, 1·19 of fat, 26·14 of non-nitrogenous extractive matter, 45 15 of woody fibre, and 15 85 per cent. of ash

The nutritive value of such a woody mass as this, he reports hardly equals that of straw or chaff.

THE *Tea Gazette* in its first issue of December has a most extraordinary leading article on "Mineral Manures." We see sulphate of iron or copperas, advocated as a manure, a Chemical that is poison to vegetable life. The *Tea Gazette* speaks further of it as an insoluble compound, while it is easily soluble in water; it speaks of salts of phosphorus and salts of nitrogen, which we have not as yet heard of, and classes nitrogen as a mineral substance. How are we to account for such blundering in the leading columns of a professedly scientific journal?

THE Neilgherry newspaper reports that a small consignment of Ceara rubber plants (*Manihot Glaziovii Muell*) have just been received from Kew. Of these 53 were sent to the Nelambur teak plantations to be reared under the care of Mr. Ferguson, and 34 are in the hot-house of the Government Gardens at Ootacamund, under the personal supervision of the Superintendent. The ultimate home for these latter is a ravine at the foot of the Kotagherry ghaut, originally prepared for the growth of Mahogany, and perhaps a couple will be tried at Burliar. Referring to this species, Colonel Beddome observes: "This Ceara has a succulent, weak-looking stem, rather suggestive of a soft wooded shrub or creeper than a tree. It is apparently a new species of Manihot, and not mentioned in the latest books on the order to which it belongs (Euphorbiaceæ), and looks as if it would grow readily from cuttings." A few plants are also to be supplied to the Superintendent Government Farm, and to the Secretary of the Agri-Horticultural Society, Madras.

FOR some time past, as our readers are aware, the Maharajah of Cashmere has given considerable attention to the development of an industry in the growing and reeling of silk, to cover to some extent the losses occasioned by the depression in the shawl trade. The efforts made have been fairly successful so far, samples of raw silk sent to England for valuation having been reported superior to Bengal, and approaching Italian silk in quality. The progress of the industry has, however, we are sorry to hear, received a severe check,—an epidemic disease having killed off most of the worms, and this season there are no eggs to breed from. The whole thing must be re-commenced. The climate is well adapted to the cultivation of silk; much perseverance and public spirit had been shown by the Maharajah's officials in creating and fostering a new industry.

IN many of the southern governments of the Russian Empire, where the accumulated droppings of the countless herds upon the steppes and plains cannot be remuneratively employed as manure for the land, they are put to profitable use in the preparation of a form of fuel, known as "kizjak," which is largely consumed in the winter months by the peasantry and smaller farmers. This kizjak occurs in the form of bricks, similar to those of peat, and so met with as an ordinary article of commerce in at least seventeen governments of the Empire. Its manufacture dates from the year 1844 only, when the system of employing the waste manure, now so general, was introduced into the Government of Orenburg by a Cossack Major named Podurow. The price of kizjak varies in the different provinces where it is used, according to quality and the local demand for it, from 1½ rouble to as much as 20 roubles per 1,000 bricks. As regards its heating power, it naturally occupies a low place in the scale as compared with many other substances, and it is generally calculated that for the production of a certain amount of caloric about three times as much of good kizjak is required as of ordinary coal. Two chief varieties of kizjak are met with in commerce, respectively prepared from horse dung (Loschadiji kizjak) and sheep dung (Owtschiji kizjak). The relative value of these as fuel depends, of course, on their chemical composition. That of an average sample of each kind may be taken as follows:—Horse kizjak: carbon, 41·386; hydrogen, 4·985; oxygen, 33·396, nitrogen 1·073; salts and earthy admixtures, 18·530 per cent. Sheep kizjak: Carbon, 28·690; hydrogen, 3·785; oxygen, 27·990; nitrogen, 1·907; salts and earthy admixtures, 37·630 per cent. In preparing either sort, the dung that has been collected over winter is spread out in thin layers on the ground, sprinkled plentifully with water, and then trodden down by horses. The paste thus made is pressed into wooden forms, like brick moulds, and then placed in the open air to dry. Occasionally the kneading process by horses is omitted, but the bricks are then apt to crumble to pieces.

IT is stated that a present to the Maharajah of Cashmere of some samples of the Cuzco maize seed, sent out from England by the Secretary of State, was forwarded, some time ago, by the India Government to His Highness for experimental cultivation in Cashmere.

WE noticed in our last issue the inferiority of the potato now produced in the Punjab hills to that once grown there. The tuber seems to have deteriorated throughout India. The Neilgherry paper says: "The glory of our Kulhutty potato has also departed. But the cultivation of this popular tuber is very general now in the villages of this district. The authorities cannot do better than distribute fresh seed among growers. A year ago, a quantity of potatoes grown in the Ootacamund Government gardens was distributed among a few Burghers and Canarese vegetable gardeners—but the tubers failed to germinate freely; whether from climatic influences or from other causes they rotted in the ground. The potatoes now brought to market are better, but still much disease is prevalent."

A CORRESPONDENT of the *Brewers' Guardian* says that maize has been successfully malted, and that beer or porter brewed from one-third maize, and two-thirds barley-malt is equal in every respect if properly brewed, to that made from barley malt alone, and is more full to the taste.

THE suitability of the soil of Perak for planting enterprise seems to be exciting more and more attention every day. We read that five or six more planters from Ceylon are now in the State examining its soil. Johore also is following suit. The Maharajah has offered Mr. Buchan, Private Secretary of the Governor of Ceylon, and formerly a planter, £1,000 a year to become a sort of Minister of Lands for Johore, and he is expected there in the beginning of this year, accompanied by four or five more planters, to explore the territory.

OUR Ootacamund contemporary lately suggested that as barley does so well on the Neilgherries, a quantity of fresh seed should be procured and distributed among the Burghers; this we are now told has been done. The present proprietor of the Castle Brewery gratuitously distributed 1,000 bushels of seed barley among the Burghers of the Arvanghat valley, in the early part of the year. The only condition imposed was that the produce should be sold to the brewery at a rate agreed upon. The Burghers, however, consumed the produce of their fields, and excused their breach of contract on the score of the prevailing scarcity. It is, however, not unlikely that some portion of the grain has been preserved for future sowing, and that at a future time, the proprietor of the brewery will be rewarded for his liberality.

A REMARKABLE instance of spontaneous combustion is afforded by a correspondent of a scientific contemporary, in which a house in Caracas narrowly escaped being set on fire through the sudden outburst of flame from a large wasps' nest in a closet under the roof. Although the weather was intensely hot, the position of the nest, under a roof composed of tiles and thick layers of earth, was such as to preclude the possibility of the fire having originated through solar heat. Suddenly thick smoke was observed to issue from the closet; and, had not immediate steps been taken to arrest the spread of the fire, a serious conflagration might have resulted from the combustible nature of the wax-cells of the nest. Similar occurrences are described as being very frequently observed in Venezuela. The temperature of bees' nests or hives is known to be very high, frequently reaching 38 degs. Centigrade or 100 degs. Fahr., being considerably more than the normal temperature of the human body. The variety of honey-collecting insect known as melipone, whose nest resembles that of the wasp, is common in Central America and the northern parts of South America, and it

is probable that their nests have frequently been taken for the nest of the wasp. The phenomenon is probably caused by some chemical change in the constituents of the nest under the influence of the high temperature, and it is possible that the same danger would await the nest of the ordinary hive-bee under favourable circumstances. The point is worth further investigation in temperate as well as torrid climates; and bee-keepers may both draw as practical a lesson from the facts related in connection with the regulation of the temperature of their hives.

A NEW process of obtaining the saccharine juice from the sugarcane has lately been invented by a Mr. A Bonnefin, of Mauritius, who endeavoured, without success, to get his invention taken up in the island. He then went to England, and has succeeded in selling his process to a Company for £32,000. The principal feature of the invention appears to be that the canes, instead of being passed entire through the crushing rollers, are first sawn up by vertical and horizontal saws into very small pieces, the result of which is said to be that not only is the power required to make a given quantity of sugar reduced by three-fourths, but, moreover, there is hardly any juice left in the cane trash. It is well known that the loss of juice in the "bagassee," or cane trash, has hitherto been very large; and it seems, by the new process, to be reduced to a minimum.

THE value of English drills in this country has been abundantly proved at the Mysore Experimental Farm. Seed can be sown in rows at any depth, and at any required distance apart. The quantity sown can, also, be regulated. And a rapid effective surface cultivation can easily be given after the crop is above ground by means of hoes and scuffles drawn by bullock-power and by hand-hoeing. The Japanese have adopted all the English implements of agriculture, but an English plough is a novelty in India and an English drill a curiosity.

A SUBSTANCE having the properties of India-rubber and gutta percha has been derived of late from the bully tree, on the banks of the Amazon and Orinoco. It is called balata. It is tasteless, gives out an agreeable odour on being warmed, may be cut like gutta percha, is tough and leathery, is remarkably flexible, and far more elastic than its rivals. It becomes strongly electrified by friction, and is a better insulator of heat and electricity than gutta percha.

MR. PEREIRA, Sur Ameen of Bangalore, in a letter to the President of the Municipality, points out that poisoning by datura is alarmingly on the increase, there having been no less than seven cases detected in November, and, judging by the apathy of the Police, this number must represent but a fraction of the actual number of cases. Datura grows wild all over the cantonment of Bangalore. Mr. Pereira observes that there are two species,—the *black* and the *green datura*. The apple of the datura contains upwards of 300 seeds, one of which is enough to stupefy a grown up person. A person who has been drugged with *datura* remains insensible for several days, which of course lessens the chances of detecting the poisoner. Mr. Pereira suggests therefore that the Municipality should undertake the destruction of the *datura* plant in Bangalore, and make it penal for any one to grow, or sell, or be found in possession of *datura*.

MR. T. SMITH (Newry, England) writes concerning the Elymus Glaucus:—"Allow me to speak a word of praise for this really distinct and useful grass. In colour it is quite unlike any other, being bluish green, and it extends itself freely in every direction. It succeeds both in wet and dry places; in fact, it seems to grow any where; and ultimately it becomes a densely matted mass from two feet to three feet high. I may add, too, that, in addition to its value from a decorative point of view, it makes a first-rate corner plant."

THE leaves of plants, considered in reference to their action on gases, fulfil two distinct functions. By their protoplasm or nitrogenous contents they absorb oxygen, and they give out constantly carbonic dioxide (carbonic acid). By their green colouring substance or chlorophyll they inspire, during the day only, carbonic dioxide gas, and expire oxygen. In the young state the protoplasm predominates, the chlorophyll is relatively scanty; hence during the period the respiratory function predominates over the assimilating function, and consequently the leaves exhale carbonic dioxide at this stage without interruption. As the leaves increase in size the protoplasm diminishes, the chlorophyll augments, consequently the capacity of emitting carbonic acid during the day rapidly diminishes, and soon they give off nothing but oxygen. From this time forth it is only by placing the plants in darkness, or by more or less suspending the action of the chlorophyll, that it is possible to demonstrate the effect of respiration. There is, then, for living beings, plants, or animals, only one kind of respiration—the same for all. The office of the chlorophyll is different, its work is one of assimilation. Such are the conclusions to which M. Corenwinder arrives in a recent number of the *Annales Agronomique*, after detailing some new experiments made by him, and summarising old ones. The views advocated by M. Corenwinder, based indeed to a very large extent on M. Corenwinder's own experiments, are now adopted in all our standard text-books; and if the contrary is still taught in so-called popular books and by ill-taught popular lecturers, it is only because the filtration of new ideas takes time. M. Corenwinder may rest assured that views are accepted by the great majority of those whose opinion would be appreciated by him.

FROM the annual report on the Nicobar Islands for 1876-77, we learn that some interesting agricultural experiments were made during the year. Arrowroot was cultivated and manufactured, but owing to the want of clear water for washing the produce, it was not considered fit for the Calcutta market. Three hundred and sixty-two bighas were planted with coffee, which promised well. A few plants of vanilla were received from Calcutta, three of which survived and grew well, and twenty cuttings taken from them struck root and were thriving. Indigo was tried, but the seed, owing probably to accidental causes, did not germinate.

THE last exotic spice which has been acclimated in California is the ginger plant. At Santa Clara the plant is growing thriftily. It resembles the corn stalk in size and appearance but unlike corn, yields a blossom. From the root is made the valuable product, Jamaica Ginger.

AN Alsace-Lorraine agricultural journal gives the following description of a method of preparing potatoes for long keeping, which is largely practised in many parts of France. A large kettle or boiler of water being placed over the fire, and its contents raised to boiling point, the potatoes, previously well washed, are placed, a few at a time, in small baskets or nets, which are then rapidly thrust under water and there retained for about four seconds. Of course, the introduction of so considerable a bulk of cold matter lowers the temperature of the water somewhat, and care must be taken that it rises to the boiling point again after each immersion before a fresh netful of potatoes is introduced. As each batch is withdrawn it must be shaken, and spread out on the flooring to dry in some well-aired place. When all the stock has thus been treated, and is thoroughly dry, it should be stored away in some dark room, of course free from damp. The potatoes will be found to have lost all tendency to germination, and will remain sound and well-flavoured till the next year's crop comes in.

COMMUNICATED AND SELECTED.

AGRICULTURAL EDUCATION IN THE BOMBAY PRESIDENCY.

THE Governor of Bombay in Council directs the publication of the following papers regarding Agricultural Education, for the information of all concerned. His Excellency in Council earnestly requests the co-operation of all officers and of the Native community in the furtherance of this important cause.

Minute by the Governor of Bombay, dated 29th October 1878.

I.—The need of agricultural science in this country, the backwardness of the people in the superior methods of culture, the slow deterioration of the soil in many places from exhaustive processes, the want of restorative means and appliances, the probability that by improved husbandry the yield of the soil could be augmented,—are considerations so manifestly important that no apology is needed, when I ask my honourable colleagues to join me in pressing them upon the attention of all concerned. Nor need I at all dilate upon them, as they are so well known to, and so fully appreciated by, my honourable colleagues.

2. Referring to paragraph 5 of Minute of the 8th September, regarding the formation of a class at Poona for training natives in scientific agriculture,—in which my honourable colleagues concurred,—I have now to mention that Mr. W. R. Robertson (Superintendent of the Agricultural Institute at Sydapet near Madras) has arrived at Poona and conferred with me and with Dr. Cooke, Principal of the Civil Engineering College at Poona on the whole subject of education in scientific agriculture. I have accordingly to state for the consideration of my honourable colleagues the conclusions to which we have come provisionally.

3. Despite the superior local advantages, respecting the productiveness of agriculture and the enterprising character of the people, which Guzerat possesses as compared with the Deccan, I find that Poona is clearly the best place for the establishment of an Agricultural College. I bear in mind that the people of Ahmedabad are anxious that such a College should be established at that city. We do not, however, at present possess the means in Guzerat, whereas we do possess them in Poona. Hereafter if the development of agricultural education shall enable us to establish a College in Guzerat, that will be well; meanwhile we must be content with making a commencement at Poona where the necessary facilities exist. At Poona alone have we at hand the scientific appliances and the teaching power for high education in agriculture. As already proposed in my Minute of the 8th September, the Civil Engineering College at Poona (which is fast developing into a College of Science) can make scientific agriculture one of its branches. The Committee, which my honourable colleagues concurred with me in appointing, have submitted their proposals, which will be found worthy of our approval, whereby only matriculated students will be admitted to the agricultural class. This class, then, will be strictly a College class, and its under-graduates will be qualifying themselves for the degrees which, we hope, the Bombay University will confer in scientific agriculture. In that case the University would fix the standard of examination. At this College will be preserved the high standard of agricultural education which students from the interior of the country may be expected to reach. Here will be placed the centre and the head of the system. From here will emanate the supervision which will be needed for whatever agricultural schools may be established in the various districts. The annual cost of the arrangement is estimated by the Committee at Rs. 6,000.

4. I may add that at Poona, veterinary instruction of the best kind can be afforded—indeed an excellent school of this kind already exists in the Cantonment.

5. In connection with the College at Poona, I propose, (if my honourable colleagues shall concur) to establish agricultural classes in some of the high schools in the several districts of the Presidency. This method will be comparatively cheap and easy: can be almost immediately carried out, and can be adapted to a very small number of students at the outset; whereas the setting of separate agricultural schools would be costly and difficult, would be beyond our means at present, and would be unsuitable if at the outset only a few students were to come forward. At a high school the students are taught English and the vernacular, also the ordinary kinds of elementary knowledge. Those among them who might be willing to attend an agricultural class could do so. Mr. Robertson thinks that one hour a-day for in-door agricultural instruction and one hour extra out of doors every other day would suffice. To that extent the students would have to be excused some of the ordinary subjects of study, the English and vernacular studies only being obligatory. After a two years course they might, in the opinion of Mr. Robertson and Dr. Cooke, receive "school certificates" of proficiency in agriculture on passing a moderate examination, which would be conducted by the Poona College. Such a certificate would *per se* be of use to a young man even if he went no further, but more particularly it would admit him to the agricultural class of the Poona College.

6. It will be remembered that to this class matriculated students will also be admitted and will be eligible for a University degree in agriculture. A certificated student of an agricultural school, as above described, will be admitted to the College class, indeed, but will not be eligible for a degree unless he passes the Matriculation Examination also. If he does not become eligible for a degree, he may, after a two years' course in the College, obtain a College certificate, which will have some considerable value; but will never be so valuable as a degree. It would be better, of course, that after having obtained his school certificate in agriculture, he should also pass the Matriculation Examination. But he may not be able to do so, and in that case he should not be debarred from the College instruction even though he may not be eligible for a degree.

7. The course for a degree will probably be determined by the University at three years. But Mr. Robertson and Dr. Cooke think that for a College certificate, as above described, a two years' course will suffice, as the students must necessarily have undergone a two years' agricultural course at the school.

8. The College then would have two sets of students—first, under-graduates going through a three years' course for a degree; second, students having school certificates and going through a two year's course for a College certificate. Young men belonging to either set will be most useful persons to the country in various capacities, official and non-official.

9. Dr. Cooke desires to open this class from the commencement of next session, that is, in November. No time, therefore, should be lost in sending round the requisite notices to the several high schools to inform intending students. The curriculum has been already proposed by the Committee above alluded to. The chemical course would be partly devoted to agricultural chemistry; the botanical course to agricultural botany; the geologic course to surface geology. For the agricultural course Dr. Cooke agrees with me in thinking that we may await the appearance of Mr. Robertson's text-book of agriculture to be issued very soon, which is based on the best English text-books, with special reference to the experience gained during several years in Southern India.

10. I revert to the organization of the agricultural classes in the high schools. It would be very desirable to open at least six such classes at various places; three of which classes might be in Guzerat, where the system is more likely to be immediately popular than anywhere else; one in Khandeish and the remainder in the Deccan. We know that many students in Guzerat are willing to come forward.

11. The first question is, whence are the teachers to be obtained? Now, fortunately, for some time past, many youths from the Bombay Presidency —chiefly Parsees—have been studying under Mr. Robertson at Sydapet, where they have nearly completed a three years' course. Mr. Robertson thinks that the best of them will, on completion of their course, be qualified to give elementary instruction in agriculture to school classes. For the six classes which we propose, then, six men would be required. After consulting Mr. Robertson, I propose that we offer each of the six young men whom he may select a salary of sixty rupees per mensem. And this would constitute the sole charge of establishment for the classes. Here, then, we have our teachers at hand. In future the Poona College will produce teachers.

12. The next question is, what shall be the curriculum? There again, fortunately, Mr. Robertson has a little book, almost quite ready, in English, on this very subject of elementary agriculture, called the agricultural class-book, based on the books published in England and adapted for the use of Indian schools after an experience of several years in Southern India. This book comprises elementary instruction in—

I. Soils.—Origin, formation, distribution, tillage.
II. Manure.—Varieties, action, uses.
III. Crops.—Varieties, culture, uses.
IV. Stock.—Races, breeeding, feeding, general management.
V. Implements.—Machines, tools, water-lifts.

As already seen these students must know English, therefore this book will suit them exactly. So much for the in door curriculum.

13. There remains the matter of the out-door curriculum, which is of primary importance with respect to agriculture. It is in the field that the students must practice the principles of which they have read in the agricultural class-book. For this purpose, Mr. Robertson thinks that at least six acres would be needed for each class; this area is a minimum; ten acres would be better; but as economy is essential, we must be content with a minimum to begin with. The six acres are made up thus—one acre would be wanted for ploughing deep and shallow; two acres for rotation of crops; one acre for exhibition of manure; one acre for irrigation; one acre for perennial crops as distinguished from annual crops. As near to the school as possible, then, six acres of land would have to be rented, for at least ten years, in order to give the experiments fair play; though a twenty year's lease would be better. Irrigable land would be preferable: but as just seen it would not be absolutely necessary that more than one acre out of the six should be irrigated; therefore the six acres may be unirrigated land if irrigable land be not available in the locality. The rent of six acres of land then at, say, ten rupees an acre, or sixty rupees in all, would be an annual charge against the class; which is moderate. There would be some initial outlay which, after consulting Mr. Robertson, I find would be wise: one iron plough Rs. 25, one pair of bullocks Rs. 80 to 100, one cart Rs. 80, implements and tools Rs. 50, but for one field labourer, and shed for a pair of bullocks, say Rs. 50; fencing Rs. 20—in all Rs. 325, to which add Rs. 100 for seeds, manure, and miscellaneous—total 425. The up-keep of the bullocks and the wages of the labourer would together amount to Rs. 30 per mensem, or Rs. 360 per annum. There would be annually recurring contingencies, but these would be defrayed from the produce of the six acres.

14. It would not be practicable at present in these school classes to afford out door veterinary instruction—though the principles of it would be taught in the class-book.

15. The annual charges then of a High School agricultural class would be thus:—

Teacher (at Rs. 60 per month.)	Rs.	720
Rent of six acres	„	60
Wages of one labourer and up-keep of one pair of bullocks	„	360
	Rs. ...	1,140.

The initial outlay would be Rs. 425. These figures have been carefully verified by Mr. Robertson. For six such schools the annual outlay would be Rs. 6,840, and the initial outlay would be Rs. 2,550. These expenses seem moderate. If the whole of them cannot in these times of financial pressure be afforded, still a portion of them certainly can be afforded; that is, if six classes cannot be afforded, we may begin with four classes, and so on.

16. The annual expenses of an agricultural class at the Poona College is, as already seen, set down at Rs. 6,000. Thus the annual cost would be for—

Schools	Rs.	6,840
College	„	6,000
	Rs. ...	12,840

and the initial outlay Rs. 2,550, say with extras Rs. 3,000. With these moderate sums a humble but sound system of agricultural education might be set on foot in this Presidency. A beginning might be thus made. If it should succeed, then the outlay might be augmented hereafter according as the demand might grow or as our financial means might increase.

17. If my honourable colleagues shall approve, the Director of Public Instruction might be requested to arrange to open the six high school classes from the commencement of the next official year, that is, in April 1879. It should be explained, however, that the teachers from the Sydapet institution cannot join till June, as they will not have completed their course and obtained their certificates until that time. However, it will suffice for them to join by the 1st or even the 15th June, when the agricultural year begins.

18. The foregoing remarks apply to what may be termed superior instruction in agriculture in the upper schools in English. Our object should further be to scatter broadcast as it were the elements of such instruction among the middle schools in the vernacular. Now, although six acres represent the minimum area on which superior instruction can be afforded, Mr. Robertson thinks that some elementary instruction, which would be much better than nothing, could be afforded to a vernacular class even on one acre. If there were difficulty in exhibiting ploughing, still the rotation of crops, some of the methods of culture, and the use of artificial manure, could be exhibited even on this small space. One teacher, trained in the superior classes above described, might in some localities serve several schools, say three; then if his salary were, as before, Rs. 60, the charge to each school would be Rs. 20, or Rs. 240 per annum, to which would be added Rs. 10 for rent of one acre and some small initial outlay, say from Rs. 100 to Rs. 200. It is impossible to estimate exactly the cost, but it manifestly will be but small; and if these classes became at all popular, the village headmen and other peasant proprietors will be sure to render help in defraying the charges. If teachers shall be obtainable, such classes would soon multiply and men will be qualified (natives of this Presidency) at the Sydapet institution by the middle of next year. In after years they will become qualified in our own superior classes. As regards the curriculum the agricultural class-book in English alluded to will be soon translated into the vernacular; or rather a vernacular class-book of a similar scope will be prepared.

19. Besides the agricultural instruction given, together with experiments on the ground, some rudimentary instruction can be given in all primary schools by means of a primer of agriculture in the vernacular. Mr. Robertson will, as I learn, be good enough to assist in preparing such a primer suited to the circumstances of this country, and then we can soon have it translated into the vernacular. When the teaching of the primer shall be established in the primary schools, some arrangements might be made for having itinerant instructors going about and lecturing from school to school, showing some simple experiments, illustrating the things taught in the primer and so on. Arrangements of this sort has, I believe, been adopted with success in some countries.

20. One effected method of diffusing a knowledge of agriculture among the land-holding classes is to ensure that our native Revenue officers and officials shall graduate in this science, the Mamlatdars, the Mahalkharis, and those Karkuns who hope for promotion to the higher grades. We are already endeavouring to arrange that all these officials shall be graduates of the University. If a degree in agriculture shall be established by the University, then a preference might be given to that degree over other degrees for this particular class of appointments. Or else it might be ordered that all officers and officials in the land revenue department must go through an agricultural course, the higher grades through the college course, the other grades through the school course, as above described. Further, as the system takes root, it will not be difficult to arrange that all headmen (Patils) and village accountants (Kulkarnis), whose hereditary appointments require the confirmation of the authorities, shall pass some elementary examination in agriculture.

21. My honorable colleagues will doubtless agree with me in acknowledging our obligations to Mr. Robertson for the interesting information and valuable advice which he has afforded us, and to the Madras Government for so kindly lending us his services for a short time.

RICHARD TEMPLE.

Minute by the Honorable Mr. Gibbs on Agricultural Education, dated 1st November 1878.

I entirely concur in the exhaustive Minute of His Excellency the President, and shall be very glad to find that funds can be provided to carry out all his suggestions.

It is quite time we instituted schools for this purpose. In Guzerat the want has been so much felt by the enterprizing land-holders in Kaira that they have availed themselves of the institution at Sydapet in Madras; and from what was said at the Conference held at Gunish Khind about two months ago it would appear that a desire very generally exists to improve the cultivation by rotation of crops, manuring, and other plans which can only be communicated by those trained in Europe; and although experience has taught the natives of this country to utilize many of the resources which nature has provided for them, still the spread of agricultural science will doubtless lead them to make greater use of those resources, as well as to find out others which, although now existing, are unknown to them.

The measure is one which seems to me likely to increase the wealth of the people in a most substantial way; and though doubtless any very great strides in this direction are not to be expected at once, still we must remember that every student who leaves such a school may be looked on as a pioneer to instruct his fellow villagers and so render his own knowledge ten-fold more valuable to the common weal.

Our thanks, as suggested by His Excellency, are due to His Grace the Governor in Council, Madras, for so kindly placing Mr. Robertson's service temporarily at our disposal; and I venture to think that not only to him for the information he has given, but also to Dr. Cook, the Principal of the Civil Engineering College, for the ready response he has given to His Excellency's wishes, our thanks are due.

J. GIBBS.

Minute by the Honourable Mr. Ashburner, dated 3rd November 1878.

I appove of the scheme for the establishment of an Agricultural and Veterinary Class attached to the Poona Engineering College.

L. R. ASHBURNER.

RESOLUTION.—In reference to the foregoing Minutes in Council the Governor in Council decides that a College class for instruction in Agriculture should be attached to the Civil Engineering College, Poona, and declared open for students who have passed the University Matriculation Examination.

Three years should be fixed for the present as the period for the course of study. The Finance Department will be asked to sanction scholarships tenable for one year, according to the list given in the next para, to be competed for (1) by the students entering the class, and (2) by those who have completed their first year. As care is necessary to prevent students joining the class for the sake merely of the scholarships, and with no serious intention of making any practical use of agricultural knowledge, the scholarships should not, as a rule, be awarded at a greater proportion than one to every candidate in the class, and the Principal of the College should have the power at his discretion to withhold them altogether should he consider the candidates undeserving of them. At the same time, within the maximum number below stated, the Principal should be given discretionary power to increase the proportion of scholarships to the strength of the class, in the case of deserving candidates whose poverty is undeniable, or who belong to the agricultural classes.

It is possible that hereafter it may be proper to reduce the ordinary proportion of one scholarship to two students, but it is important to offer to students a fair inducement to start the class.

2. The scale of scholarships proposed as a maximum is as follows—

		Per mensem. Rs.
To be competed for at Entrance Examination.	2 at Rs. 10 each	20
	2 at „ 8 „	16
	4 at „ 7 „	28
	1 at „ 6	6
	1 at „ 5	5
		75
	1 at Rs. 12	12
	3 at „ 10 each	30
	1 at „ 9	9
	4 at „ 8 each	32
		83
	Total per mensem ... Rs.	158
	Per annum ... Rs.	1,896

3. The scholarships according to this scale, even if all awarded, will cause an expenditure less than that proposed by the Committee by Rs. 744 per annum; and the Governor in Council being of opinion that it is of great importance to add a course of Veterinary Lectures to the instruction to be given in the class, would allot Rs 660 for this purpose—Rs. 300 being assigned for 25 lectures to students of the first year, and Rs. 360 to 30 lectures to students in the second year.

4. In respect to the establishment of agricultural English classes at six of the High Schools in the Presidency, the Director of Public Instruction is requested to take steps in accordance with the principles laid down in the Minute by His Excellency the Governor and to submit proposals in detail after local enquiry. The several Commissioners and Collectors are requested to aid the Director in this important matter to the utmost of their ability.

5. A similar instruction is applicable respecting the establishment of Vernacular Classes according to the principles laid down in the Minute.

By order of His Excellency the Honourable the Governor in Council.

C. GONNE,

Secretary to Government.

BONES AND SUPERPHOSPHATES.

PLEASE answer the following queries:

1.—What chemical changes take place when 100 pounds of raw ground bone are dissolved with sulphuric acid? Is sulphate of lime (gypsum) formed, and what proportion?

2.—Is bone made more available for plant food by the use of acid, and if so, why is it ever used undissolved?

3.—What is the difference between, and relative value of dissolved bone and dissolved South Carolina rock?

4.—Is it advisable to mix gypsum with superphosphate before using, or is there a sufficient quantity already present?

5.—Is it proper to mix wood-ashes with hen-manure, and if not, what are the chemical changes that make it improper?

6.—Is the strength of the odour from a superphosphate a good test of its agricultural value?

7.—In an analysis like the following, where only from 13½ to 18½ per cent. of available chemicals is given, what is the probable value of the balance of the 100 parts for agricultural purposes?

Available phosphoric acid	8 to 12 per cent.
Ammonia (potential)	2 to 2½ ,,
Potash (K.O.)	3½ to 4 ,,

You will oblige me and probably many others, by giving full and practical answers to the above.

C. L. L.,
Berryville Va.

[*Answer by* Prof. S. W. Johnson, *Sheffield, Scientific School.*]

1.—Raw ground bone is somewhat variable in composition, but contains about as follows:—

	Per cent.
Water	10
Organic matter, gelatine and fat	30
Sand and impurities	4
Phosphates of lime and magnesia	50
Carbonate of lime	6
With nitrogen	3
With phosphoric acid	24

When finely ground raw bones are treated with somewhat diluted sulphuric acid, they are not dissolved, in the strict sense, but they are disintegrated, and their phospates are so changed chemically as to be dissolved upon adding a large quantity of sulphuric acid that is used. For agricultural purposes, the point is to render a good share of the phosphoric acid soluble in water as cheaply as possible. To accomplish this, the bones must be mixed with diluted sulphuric acid, enough to take away from the bone-earth (tricalcic phosphate) two-thirds of its lime, making therewith sulphate of lime (gypsum), and leaving superphosphate of lime (monocalcic phosphate). Before the sulphuric acid will touch phosphate it must decompose the carbonate present, converting its lime into sulphate. Six pounds of carbonate of lime require, in round numbers, 6 pounds of oil of vitriol for this purpose, and the product will be 8 pounds of gypsum. To convert the 50 pounds of phosphates into superphosphates will require 26 pounds of oil of vitriol, and the result of this conversion will be 40 pounds of monocalcic phosphates and 48½ pounds of gypsum. The 55 pounds of phosphates and carbonates will thus yield, with 26 pounds of oil of vitriol, 56½ pounds of gypsum and 40 pounds of monocalcic phosphate. The excess of the latter 96½ pounds over the former 82 pounds is due to 18½ pounds of water, which the gypsum and the monocalcic phosphate take into chemical combination, and which is provided for by diluting the sulphuric acid with twice its bulk of water before mixing with the bone. The above result is never quite reached, because, owing to the coarseness of the bone and the bulk of the gypsum formed perfect admixture and contact between the phosphates and the sulphuric acid is not attainable. More sulphuric acid will effect complete solution of the phosphoric acid, but in practice that is not advisable.

2.—Bone is certainly made more available as plant food because it is made more soluble, and thus admits of immediate distribution to the soil. The effect is not to make the phosphoric acid any better for the plant, but to make a given quantity of it to feed more plants in less time than would happen with bones not sulphated. The nitrogen of the bones is also rendered more rapidly accessible to plants by this treatment. The ultimate effect of acting on bones with sulphuric acid is the same as that of extreme pulverization. Bone flour is as actual and effectual a fertilizer as the sulphated bone. The reason why bones are ever used undissolved is simply because under many circumstances it costs less to do so. In other words, a given amount of money and labour expended in raw bone often goes further and does better than when put into sulphated bones.

3.—The difference is, that dissolved bones contain 2 to 4 per cent. of nitrogen of which South Carolina rock is destitute. The relative money value depends of course upon how they are made, or what quantities of nitrogen and soluble phosphoric acid they contain. Nitrogen in sulphated bone is worth 20 cents. per pound in our commercial centres, while soluble phosphoric acid is worth about 12½ cents. The relative fertilizing value depends upon the soil and crops they are applied to. When nitrogen alone is needed to make a crop, the South Carolina rock would, of course, have no fertilizing value.

4.—There is no occasion to add gypsum, unless more is wanted than the usually small dose of dissolved bone would supply.

5.—The white portions of bird dung consist of *urate ammonia.* If mixed with quick lime, ammonia, will be copiously set free, and go off as gas, urate of lime remaning; but if the mixture be mixed and covered with abundance of moist loam, the ammonia will be retained in the latter.

6—.No; none whatever. The richest superphosphates may be quite free from strong odour.

7.—Eight to twelve per cent. of available phosphoric acid usually implies 40 to 23 per cent. of gypsum; 2 to 2½ of potential ammonia implies 30 to 40 of animal matter, and 3½, to 4 of "potash" implies 8 to 12 of sulphate or muriate of potash. Then 20 per cent. of moisture, and 1 to 5 of sand or soil, are practically inseparable from most commercial fertilizers.—*Montreal Herald.*

CULTIVATION OF CAROLINA PADDY.

In the latest published report on the working of the Sydapet Farm, Mr. Robertson devotes a whole chapter to the subject of Carolina paddy and the experiments made in the presidency to introduce it. Since the past ten years, the Government have done much to encourage the growth of the paddy, and with that view imported supplies of the best or "gold seed" from America. About four hundred bushels of the Carolina paddy seed were sent to Madras and distributed gratuitously over all parts of the presidency. From the reports submitted by the Tehsildars and Collectors of the districts under whose observations, experiments were carried on, it appears that in some cases good crops were obtained. The opinion advanced that the climate of Madras is unsuited to the cultivation of Carolina paddy, is considered untenable. Mr. Robertson holds that by the Indian cultivator adopting an intelligent system he may "secure to the plant those good agricultural conditions which in America is invariably met with." In the experiments carried out in this presidency, the land was not properly manured except by the silt deposited by irrigation water, some plots were puddled and worked according to the native system which is highly objectionable. It obstructs the passage of the irrigation water through the soil. The system adopted of preparing nursery beds was also objectionable, and hence a "difficulty was experienced in pulling up the Carolina paddy plants for transplanting." The irrigation of the crop was conducted in the ryot's own fashion. No care was taken of the plants during growth besides a little weeding: the practice of hoeing is almost unknown to the cultivators—the entire absence of tillage operations is one reason, why the results in certain cases were unsatisfactory. The ears of the paddy were one-third to one-half heavier than those grown in the country under similar conditions—the average number of grains in an ear varied from 150 to 200, while many plants had from 10 to 12 fertile ears. The ryots complained that there was difficulty in separating the grain in threshing. More labor has to be expended in threshing Carolina, than country paddy; but the system adopted in this country is such as to produce a great deal of waste. No benefit is likely to result unless labor and pains are bestowed on any undertaking. In the threshing of Carolina paddy, it is necessary to spend some labor, especially as the results are most encouraging, and the yeild largely in excess of the country produce. All the experimentors were agreed upon the fine size of the grain; they were agreed as to the yield being larger than country paddy, and they found that the straw produced was stronger than any of the indigenous varieties, and valuable as fodder for cattle: other ryots however reported that their cattle refused to eat the straw as it was coarse. The fact was lost sight of that the Carolina paddy plant was able to withstand rough weather better than the country paddy, "storms that would prostrate crops of country paddy, would pass over crops of Carolina paddy harmlessly." A tabulated return was prepared of the yield of the paddy: in some cases it, was very much larger than any description grown in the country and in others, it was higher than the average yield in South Carolina. Supplies grown in Madras and in the Sydapet farm, were forwarded to England to be sold in the market there as an experiment. The price realised was not high, but the Brokers reported that if it is to be successfully introduced into the London market, it must be of better quality and be properly cleaned. The conclusions drawn by Mr. Robertson from the reports of experiments carried out are, that Carolina paddy can be grown successfully in the Madras presidency with care and proper management; past experiments were unwillingly undertaken, and consequently many unsatisfactory results were obtained. That the yield varies according to the care bestowed on a crop is amply borne out by the fact that, in one district, the yield on a certain field was 30-fold and in an adjoining district 120-fold. There are of course

difficulties in the way in growing a new description of grain in the country—that difficulty says Mr. Robertson was felt when the rice crop failed in Italy in 1829, and when seed paddy was introduced there from Carolina. The paddy which grows so luxuriantly in South Carolina, was introduced there from Madagascar, and it is suggested that instead of sending to America for seed for further experiments, supplies should be had from Madagascar. In any case, a great deal will depend upon the manner in which the grain is prepared for the market, as the high price obtained for the Carolina rice in London, is attributed to the way in which it is prepared and sold. It was intended to publish Mr. Robertson's report on paddy cultivation in the shape of a Manual or Guide, for distribution in different parts of the presidency, especially in those districts where experiments were properly made. But that intention has not been carried out as yet : a concise Tamil translation of this interesting paper will be very useful in disseminating among the ryot classes valuable information as to cultivating Carolina paddy.

MISCELLANEOUS NOTES.

THE PLANTING OF EVER-GREENS.

THESE may be planted at all seasons of the year with equal success. One of the principal things to attend to is to fix on a dull day for winter planting, and on a moist day for spring and autumn planting. Prevent their roots from becoming dry when out of the earth. Poor land, strange to say, which has been trenched and ploughed and proved unable to yield a crop of grain, if planted with ever-greens for a few years, becomes fit for agriculture.

NIGHT-SOIL AS MANURE.

THIS as most planters are aware, is a very powerful manure, liable to decompose, and abounds in carbon, hydrogen, azote, and oxygen, and in whatever state it is used supplies abundant food to plants. Of course the smell is disagreeable, but this can be cured with quicklime. Many people do not know, however, that if sprinkled with quicklime in fine weather it dries and is easily pulverised. The Chinese have much practical knowledge of manures, and they mix one-third of fat with it, make it into cakes and dry it in the sun. In this state, it is pulverized and delivered in the furrow with the seed. This is in effect desiccated night-soil, and is sold in French commerce as *poudrette*. This valuable manure is distributed over the hop-grounds of Kent. For stimulating tea plants the Chinese use it generally mixed with "ox-horn" grindings, to prevent the too rapid decomposition of the animal matter.

CHICORY AS A SALAD.

ONE of the easiest grown salad compounds in India is chicory and in the opinion of Dutchmen in Sumatra and in Java it is superior to lettuce. Garden cress is also easily grown, but one seldom can get a gardener to attend to it. At a time when eight annas is asked for a moderate sized cabbage in the Madras market, we think it is about time, that, Europeans got something out of their compounds, other than the by no means succulent grass and weeds usually luxuriating in them.

ANALYSIS OF THE TOBACCO STALK.

PROFESSOR DAVY of Dublin, went into this matter, and found that the presence of the tannin principle could not be detected and the alkali afforded was not very considerable. One thousand parts of the stalk yielded fifty-eight of ashes, which afforded three parts and a quarter of alkali, mostly potash. The stalks contain nearly one-tenth of this weight of tobacco : and where tobacco is employed either in fumigating or in making decoctions for the destruction of insects, ten parts of the stalks will produce effects equal to one part of the leaves.

AGRICULTURE IN EGYPT.

THE state of agriculture in Egypt may be compressed into a "birds-eye-view" by any traveller versed in the slightest degree in agriculture. Rice is sown from March to May, and is, 6 months in coming to maturity. The plants are spread in thick layers (as no flails are used) on floors of earth and pigeon's dung, and are well beaten. When the rise of the Nile causes a great *expansion* of the waters the *profit* of the proprietors increases 50 per cent., as the land produces 80 bushels to one. There is no saying how an "expansion" of irrigation might enrich India.

CONCERNING IRRIGATION.

THE art of irrigation consists in floating *not* in soaking or drowning, as most people appear to think in India. A constant discharge or succession of water such as would be produced by a downpour of rain is as good an example of irrigation as we can give, but this is not sufficient ; neither will it do to dam up water and make a field like a pond, such as we often see in India. Wherever the natives of India in the matter of water are taught the difference between wilful waste and woeful want, the better. It must be borne in mind, that well irrigated fields should enjoy the element of air as well as water. To get this, water must be passed over the land with a brisk current. To see a lot of buffaloes wallowing up to their knees and ribs in a so-called stagnant irrigated field is one of those peculiar features in Indian native farming economy, which would strike a Chinaman as tantamount to insanity.

No wonder that in India the income of the native peasantry averages only £2 per year. According to a recent Government report, they admit themselves, that, the most an ordinary ryot makes is 16s. per month. It is all very well to cling to the notion, as most ryots do, like the Persians, that, the earth is motionless and the sun, moon, and stars revolve round it. But for Indian Government officials to go on collecting—collecting—collecting from people so grossly ignorant of agriculture as the Indian ryots, without improving their condition, is to emulate Turkish rule. The Holy Land, once the richest country in the world, is now the worst cultivated and pays only a quarter of a million sterling. Viewing the state of agriculture in India, we fail to see how the average Indian official can be supposed to be in possession by experience of knowledge to enable him to teach the Turkish peasant how to improve his condition.

C. W.

Madras.

AGRICULTURE IN NORTH BEHAR.

(Concluded from the Agriculturist or December.)

MR. REID gives the following account of steps that have been taken from time to time to improve the agriculture at Behar A few seers of American cotton, Carolina paddy, and maize seeds he states, were circulated some years ago by Government amongst the planters ; and a ram, supposed to have some English blood in his veins, found his way to Hutwah when the estate was under the management of the Court of Wards. Here and there some teak trees, and near Mozufferpore the tallow tree, may be seen by the road side ; and at Poosah is to be found the tobacco farm. This is all that has been done by the Government to improve agriculture and arboriculture in North Behar. The indigo planters have introduced English ploughs, steam cultivators, thrashing machines, Thomson's sugar mills, and portable engines with improved pumping machinery into the province.

Many years ago the sugar industry was started by Europeans in this province on a large scale, and most expensive machinery was imported ; superior kinds of cane too were introduced, but the whole business collapsed in a few years, and ruined those who had embarked in it. So far indigo is the only agricultural industry which has benefited the European settler.

I find that sub-soil ploughing has a most remarkable effect on the few crops I have grown in fields so treated. To show my ryots what can be done by deep cultivation and green manuring, I sowed three beegahs of light sandy land with common country maize, having previously manured it with 16 tons of refuse indigo plant per acre, and sub-soiled it. Fortunately for me there is a shepherd's field adjoining mine, and he folded his sheep thereon for three months before sowing it with maize. The two fields were sown on the same day, the 26th of June, at the same time with several other fields belonging to native cultivators, which had not been manured. It did not take long for the manured fields to pick themselves out from the ruck, and the crops in them are rearing their heads several feet above their neighbours. But my field is conspicuous above the shepherd's for the more healthy appearance of the crop *and the deeper shade of its foliage.* I shall invite the attention of the Collector of the District to this field to show what can be done by improved culture, even with native seed. In 1876 I produced from a plot of land an average of 36 maunds 6 seers of grain per beegah of 32,400 square feet ; the produce consisted of 16 maunds 13 seers of wheat per beegah from the *rubbee*, and 19 maunds 33 seers per beegah of Indian corn from the *khureef*. The plot of ground selected was an old indigo field. It is not unusual for a planter in these districts to get 2,100lbs. of wheat per acre from his land, and it must be remembered that he only sows a few acres for home consumption, generally selecting the poorest soil that requires a rest and change from indigo. And yet we know that 1,100lbs. is a very good average for the ryot to get in a favourable season from his *khureef* and *rubbee* crops put together. I shall now endeavour to place plainly before you the reasons why the soil has

deteriorated under the native system of cultivation. To begin with, the assemblage of the peasants in large villages is one of the greatest bars to improved agriculture. In olden times when the country was infested with tigers and dacoits it was absolutely necessary that ryots should club together in villages for mutual protection. But now that life and property are secure, any steps that are taken towards making the cultivators live more in the fields with their cattle, instead of tethering them up in villages, will confer a lasting benefit on the agriculture of the country. At present the dung and ashes are collected in exposed heaps opposite the huts, or very often near cess-pools, rivers, and ditches, and as the surface drainage of the villages always leads into the cess-pools from which the earth was taken for the walls of the houses, every shower of rain sweeps the essence of the manure into these hollows and watercourses. Besides, by tethering the cattle and other farm animals in the villages, their urine is completely lost to the fields and goes towards making the saltpetre for which poor wretched Behar is famous. Dr. J. Forbes Watson, in a report prepared for the Philadelphia Exhibition of 1876, mentions saltpetre as "another characteristic Indian produce." He might have added that it is characteristic only of wasteful extravagance, and the most slovenly system of farming practised in the world. The saltpetre of Behar is made from the surface earth of the village sites, which are impregnated with decayed organic matter. In North Behar there are 15,947 saltpetre works and 1,304 refineries, which produce annually 500,000 cwts. of material for exportation. Besides this amount of saltpetre about 100,000 cwts. of a saline composition named *khari* is also produced yearly in these districts. It is made from the earth known as *reh*, which effloresces in exhausted lands deficient in organic matter, and this is how it is prepared for market. Straw is placed on the ground and covered with saline earth to the thickness of about four inches. The straw is then burned, and the burned matter is again covered with a foot of straw, which is also burned: this process being repeated seven times, after which the heap is covered with vegetable matter for the last time and burned. The saline matter is then dissolved in water and boiled, and by this process *khari* is produced. The waste of straw and leaves in preparing the saltpetre and *khari* is enormous, and at a very low average. I estimate that 91,400 tons are used as fuel in this business, the ashes of which never find their way back to the fields......... ...

At least twelve per cent. of the cultivated lands of North Behar are annually sown with most exhausting crops, which cannot thrive without heavy manuring. And these crops, besides taking up the best lands and nearly all the available manure of the country, are in themselves *non-manure producers*. Therefore, as a natural consequence, they thrive at the expense of the cereal crops. I now give a list of the principal non-manure producing crops, with a memorandum showing the approximate area taken up by them :—

		Acres.
1	Poppy	173,133
2	Flax, Mustard, and Safflower	400,873
3	Sugarcane	44,000
4	Cotton	52,000
5	Sunn, Hemp and Putua	13,986
6	Tobacco	41,116
	Total ...	725,108

The high rates of interest charged for petty advances to cultivators prove another drawback to improved agriculture. The usual rates are 37½ per cent. for money transactions and 50 per cent. when the transactions are in grain. I have known 100 per cent. to be exacted for grain transactions. I do not believe that there is one ryot in a thousand free from debt.

Insecurity of tenure, and the want of a proper system in keeping village rent accounts, are also great drawbacks to an improved system. The proprietors are, as a rule, most unscrupulous and grasping; and the more wealthy amongst them leave their affairs to be managed by native underlings, who are a shade worse than themselves.

There is great popular belief in the deterioration of the soil and diminished crops. The ryots, when questioned on the subject, will answer: "In former years we used to get heavy and seasonable rains, and the crops were sown and gathered without any extraordinary labour. The fields used to be full of weeds, and when the rains commenced we simply had to plough twice and plant out the paddy, and we reaped heavy crops. But *now* we plough eight times, we carefully remove all the weeds, and even with all this hard work the crops refuse to grow as they used to." The natives also say that in days gone by the mango trees bore fruit regularly every year, but now they bear only every second year. This may be only a popular tradition. But still I would not be surprised if it was the case, as certainly the mango groves receive most atrocious treatment at the hands of the native cultivators; and it is surprising to me that they bear any fruit at all. To my certain knowledge the soil has deteriorated, and the crops are worse than they were when I first came to the district. Large tracts of land that used to bear crops of rice twelve or fourteen years ago are now given up to that pernicious *kodo* millet; and no better proof than this is wanted of the deteriorated state of the soil. Besides, a glance at the prices now ruling for the different kinds of grain will prove that the land does not produce so much as it used to. Bumper harvests mean low prices in these parts.

I have many suggestions to make for the improvement of the soil and of the condition of the people. These suggestions are certainly not disinterested, as they hinge on increased support to be given to planters and other non-official Europeans, as I am certain that without their guidance and assistance the natives will never better themselves or their country. The loss and waste by the present primitive system of agriculture are incalculable, and yet the Indian ryot takes upon himself to grow crops, with his limited means and scanty supply of manure, which a European agriculturist would not think of cultivating unless he had money and manure to assist him. The result of the ryot's abortive effort is, as I have already pointed out, the rearing of these exhaustive non-manure producing crops at the expense of the cereal crops of the country. I style the ryot's system of cultivating these crops abortive, advisedly, as the average produce is only one-quarter of what is produced in other countries where intelligent management is brought to bear upon the cultivation of such crops, as sugarcane, cotton, flax and mustard. And, when we take into consideration the millions of acres that are devoted to these crops throughout the length and breadth of British India, my suggestion to check this sinful waste of good land should not be treated merely as the Utopian dream of an interested adventurer. There is no reason why the sugar and cotton crops should not produce as largely in India as in other countries, and yet we find the average produce of sugar in India is 12 cwts. per acre against 50 cwts. in other countries, of cotton in India 50 lbs. per acre against 200 lbs. in other countries. And this state of things will go on until the end of the chapter if the Government does not interfere. The question will naturally arise: Why don't Europeans turn sugar and cotton planters in India if the produce can be increased so largely? The answers to this question are several: *1st*, the European has an impoverished soil to deal with in the first instance; *2ndly*, the Indian species of sugarcane have so deteriorated that the European would be a ruined man before, he improved them; *3rdly*, the cost of the plant and machinery of sugar works is so excessive that the European planter in India could not afford to work at a loss until he had improved the quality of the cane and increased the fertility of the soil. *4thly*, the sugar industry has not received the same fostering care from the Indian Government that has been bestowed on it by the Governments of their countries. *5thly* the cheap gúr and sugar of native production would drive the Englishman's sugar out of the local markets, as he cannot produce so cheaply as the native cultivator; and if he went in for making the same inferior articles, the markets would soon be glutted.

The same arguments apply in a great measure to the cultivation of cotton. Besides, the native ryot has very hazy ideas of the difference between *meum et tuum*, and the planter would find his fields robbed of half their cane or cotton if strict protective measures were not ensured him by the Government. The thieving propensities of the natives are the great drawbacks to Europeans engaging in a general system of farming in India. Indigo has escaped them in a great measure, as they cannot eat it, and they cannot manufacture it without fear of detection. However, these questions arise—first, should the indiscriminate cultivation of these crops be allowed; secondly, should not Government interfere and insist on the weeding out of all lands that produce less than 25 cwt. of sugar and 100lbs. of cotton per acre. To accomplish these objects licenses must be granted for the cultivation of these crops, and in these licenses it should be particularly specified that the straw and dung and ashes produced from the cereal crops *must not* be used as manures for these special crops. The lands reserved for the non-food-grain, non-manure-producing crops should be made to produce all the manure required, which either may be dug in or eaten on the land before sowing; or else extraneous matter such as *marl*, artificial, and mineral manures should be used. If these suggestions were acted on and improved upon, half the area of cultivated land that is now occupied with sugarcane and cotton, would suffice to produce the same quantity that is now made all over India.

Flax, mustard, safflower, castor and other oleaginous seed plants take up a vast area of the best cultivated land, not only in North Behar, but all over India. A superficial observer does not notice these crops so much, as they are generally mixed with the cereal crops of wheat and barley; but still the immense local consumption and enormous exportation from the country will prove that these crops are cultivated in a slip-shod manner to an alarming extent. Under the present system of cultivation these crops are a curse to the land, and yet no other crops could be made more beneficial to the agriculture of the country. The stocks of these plants are used as fuel; the seeds reserved for Home consumption

are sent to the village oilman, and the surplus stock is sold for exportation. The ryot gets back his share of oil, which contains no mineral matter, but the valuable manurial oil cakes are reserved by the oilman as his perquisite. If the ryot wants oilcake for his cattle he has to buy it back again, but as he is generally too poor to do that, he has to go without it. The oil cake is therefore sold to those who have set up trading carts. The trade in these districts is most active by bullock cart traffic. The roads are nearly all unmetalled, but they are well bridged and in good working order. Forming a low estimate of the number of carts in North Behar, I should say that there are fully 60,000, the bullocks of which are never tethered in the fields, but on the roads and in houses, consequently all the oilcakes these cattle consume is lost to the soil, except the very small quantity of ash which is saved from the cakes of burned cowdung. Under these circumstances it must be apparent to every one that the oleaginous seed crops are now a burden to the soil, and yet, what a blessing they could be made. Take flax, for instance, if it were sown separately for fibre as well as for oil, from well selected seed, a new industry would be started which would afford employment to thousands of the poor during the slackest season of the year. Moreover, there would be no waste of manurial substances by the process of preparing flax for market, as the flax water is a most valuable fertiliser, and the dry chaff when worked up along with fermenting farm yard dung will pass into a good mould. The fine fibre or thread of flax takes nothing out of the ground, as a bundle of well dressed flax will leave no ashes when burned. And again, if oil-mills were established throughout the country, and the exportation of oil seeds stopped, India would keep all its oilcake for the soil, and export oil which contains little or no mineral matter. This is a subject which deserves the most serious attention from the Famine Commission. The trade in oil seeds sprang up about the time of the Crimean War, in consequence of the closing of the Russian Ports, and has made most alarming strides of late. The total trade in grains and seeds increased in value from £3,850,000 in 1857 to £13,560,000 in 1877, or about 274 per cent., and it now constitutes 23 per cent. of the entire exports. I see nothing but ruin staring India in the face from the nature of its export trade. What does the poor starved soil get back for all the saltpetre, oil-seeds, cotton, sugar, opium, and tobacco robbed from it, and sent across the seas? For besides having to supply its own teeming population with these common necessaries, it also enters into a large export business of an exhaustive nature; moreover, it buys back its own cotton, in the shape of piece goods from England, to the tune of sixteen millions sterling per annum. One would fancy the cotton was sent backwards and forwards from India to England to be seasoned, or at any rate that the country was too thinly populated to admit of the cotton manufacturing industry being started on a large scale! No wonder that all this blood sucking has at last weakened the paitent, and laid him on his beam ends. And yet the only crop which is cultivated at all on rational principles, and which acts as a tonic to the impoverished soil, is made the subject of most bitter attack by the local Government and some of its officers. Sir Ashley Eden's persistent attack on indigo always reminds me of the fearful onslaught made by Mr. Winkle on the small boy. There are bigger and more worthy foes scattering the salt of India's soil to the winds of Heaven, and yet Sir Ashley expands himself in squaring up to a miserable 2,000,000 acres of indigo land. Indigo is the only crop which returns any vegetable matter to the soil in Behar. It is a leguminous plant, growing to the height of five and six feet in favorable soils. It is always cut green, two cuttings being obtained in the year. The refuse plant and indigo water act as most valuable fertilisers. Being a legume it absorbs a considerable amount of ammonia by the leaves, and a field in which indigo has been cultivated is enriched with nitrogen. Besides, all that this luxuriant growing green crop sends out of the country is 20lbs. of dye per acre!

At the very feet of the royt's fields lie the material to turn the country into a garden. For instance, in Chumparun there is a chain of shallow lakes covering an area of 139 square miles, with a layer several feet thick of rich fertilising marl. And again, there are the magnificent fodder crops of the East, such as the *Sorghum saccharatum, sorghum vulgare*, and others, which are the most luxuriant growing grasses in existence, capable of producing unlimited supplies of fodder and manure. But a long purse, low interest, and a guiding hand are required to develop these resources.

I cannot say that free trade principles have improved the condition of the royts. Being notoriously poor and improvident they have sold their grain in seasons of plenty, and starved in seasons of scarcity. The most extraordinary thing connected with the Indian grain trade is the rapidity with which prices fluctuate from cheap to famine rates. Barley may be selling to-day at one rupee per maund, and six months hence it is not procurable at half that rate. And we can rest assured that when the price of grain is verging on famine rates, the cultivators are not the men who profit. *They* are the great *consumers* in the country and, as at best they only produce enough to keep body and soul together, it is *their* object (if they could only act upon it) to keep their granaries *full* and prices *low*. At present the *mahajun* is the ruling spirit of the age, and he has grown fat at the expense of the Government reputation and the masses of the people. It is sinful the way these men are allowed to deal with the people, more particularly in grain transactions, and as much as 100 per cent. profit is as often as not made by the village grain dealers. The months of June, July, and August comprise the season during which the agriculturist is hardest pinched for food. He borrows freely during that period from his *mahajun*, and in September has to pay back 50 for every 40 seers of grain borrowed—very often 60 seers are exacted. An energetic *mahajun* who goes in for quick returns may double his capital within the year. Now, I have to propose that the Government put a stop to these usurious transactions once and for ever by opening its hand, and establishing grain stores throughout the country, which stores would eventually prove pillars of strength to the State. There is no occasion for Government to have a separate establishment for this business, which might be entrusted to trustworthy planters and zemindars. The transactions should all be done in grain; and the grain stored should only be the hardy millets of the country, which are never attacked by weevils, and which keep sound for years without spoiling.

The store-keepers should be bound down not to sell this grain, but to exchange it in kind at reasonable rates. For instance, a royt borrowing 40 seers of grain in June would return in September 42½ seers. And if this system of quick returns in kind at favourable rates is introduced, the stored grain will accumulate at such a rate that in a few years there will be enough to feed the whole population even in the worst of seasons.

The breads made from the *murova* and *cheena* millets are wholesome enough, though tough. No loss by wastage arises from storing these millets, even though they should be kept for thirty or forty years. I beg of the Famine Commission to think of the reputation gained by Joseph for his wise precautionary measures; and the Commission should not be above taking a hint from one who successfully combated against a seven year's famine in Egypt.

I have now to recommend the planting of more fruit trees, such as the jack, muhwa, and mango. During the present season of distress I have particularly noticed the important part played by these fruits in staving off famine from the ryots' doors.

There are many estates under the management of the Court of Wards in this province, but to my certain knowledge no experiments worth being recorded have been made in agriculture, and the improvements introduced have been more in the direction of adding to the numerous roads of the province, or building new palaces and bazars, and laying out pleasure grounds.

The irrigation canals of India are the offsprings of an impoverished soil deficient in organic matter. It was only when we found that our lands would neither attract or retain moisture that we commenced to shout for canals. If I were proprietor of Behar I would not have an irrigation canal in the place, although I would always keep the natural water-courses full of water. But as I am not proprietor of Behar, and have no means of stopping the great waste of cow-dung and vegetable matter which goes on in the province, I see seasons of drought and partial rainfall looming before us; and therefore on the principle that half a loaf is better than no bread, I have raised my voice with the best of them, and shouted for canals. Eighteen years ago, when I first came to the country, the planters would have scouted the idea of having canals in North Behar, but for the last four or five years they have been begging and praying for them. There is no stronger proof required than this deterioration of the soil; and I again repeat my well-worn dirge that deficient rainfall is caused by an exhausted surface soil. Irrigation is our *last* resource.

I have, this year, seen what I never saw before, and that is, numbers of large trees dried up by the roots for want of moisture; and I have no hesitation in saying that this would not have happened if the leaves had been allowed to rot on the ground, instead of being swept away as they fell.

It is not likely that any large area of the cultivated lands will ever become waste again, and neither is it desirable that this should happen, as the wild grasses of India are of a very bad quality; and even where the cattle are plentifully supplied with them they never seem to thrive, but are to the last degree wretched. These grasses were only valuable in promoting *humus* in the soil to act as an attractor and retainer of moisture. Now, that there are no longer large tracts of waste land, it is positively imperative that we should copy the laws of Nature and promote organic matter in the soil. When a piece of old waste land is broken up it is black with *humus*, but in a very few years after it has borne cereal crops, under the present spoliation system of Indian farming, it becomes almost as white in colour as the palm of my hand. In my opinion no laws can be too stringent which are framed with the object of stopping the enormous waste of vegetable matter. Even should the natives rebel against the new innovations I would fight it out with them, and make them adopt measures to restore the fertility of the soil. Is it a fact that we are afraid of the natives of India, and are obliged to pander to the wilful prejudices of an ignorant body of peasants, who have already succeeded in rendering arid the once fertile lands of Hindostan?

In neglecting the agriculture of this vast land we are proving false to our self-imposed task of governing India for India's sake; and we shall have to answer before God for this wilful neglect of our duties. Let us, however, rouse ourselves before it is too late, and endeavour to remedy the immense harm already accomplished. Remember that it is a glorious undertaking, more glorious in its object than all the British ends of justice, canals, and railways which have hitherto been crammed down the unfortunate native's throat, as it is the only real preventive of famine; and by taking Hindoo prejudices by the horns now, and wrestling with them successfully, we are conferring a lasting benefit on future generations. Really, from the way we have hitherto managed India, one would think that we farmed it for a certain term of years and were trying to make as much as possible out of the wretched land during the short period of our lease.

The natives must be made to set more value on the vegetable produce of their fields. From the little cow-boy, who burns bundles of grass to keep the flies away from his cattle, to the high caste orthodox Hindoo, who consigns the ashes of his relatives to their last resting place with the aid of cow-dung and mango wood, they must one and all be taught, *that it is the wholesale burning of the produce of the soil which has* brought these seasons of drought to the arid plains of India. The *arhar*, cotton stalks, and maize roots are more than enough to supply fuel to the inhabitants, with careful management, *without the aid of a single cake of cow-dung*; as, at a very low average, I estimate that 2,700,000 tons of *arhar*, cotton stalks and maize roots are produced yearly in these districts; whilst the consumption of fuel for a population of 7,889,381 souls should only be 2,535,864 tons per annum; this is at an average of 60 lbs. per month for each inhabitant, which is very high.

All the villages in the province should have distinguishing brands for their cattle, and all cattle and buffaloes should be marked. Respectable natives are at present obliged to tether their cattle in the villages, instead of folding them on the fields, for fear of cattle-lifting. A recognised system of branding cattle would do away with this evil.

I shall now draw this paper to a close, as I have done my best to expose what I consider to be the most prominent evils connected with agricultural India. I have expounded ideas which will of course be pronounced wild and Utopian by the average Indian official, but still

I have noticed that these gentlemen meet every suggestion made for the improvement of Indian agriculture with the same argument. The ideas of these obstructive gentlemen are well described by a writer in the *Agricultural Gazette of India*, as follows : "These men seem to imagine that India is exempt from the operations of the laws, to which the remainder of the earth is subjected, or that these laws affect India in some special or peculiar way; they appear to think that the principles, which should govern agricultural practice in India must be specially Indian." And, therefore, if I have offended the dignity, or roused the ire of any one of India's hereditary legislators, all I can do is to ask him to remember the following lines from an old English drama :—

Pray, Goody, please to moderate the rancour of your tongue,
Remember, when the judgment's weak, the prejudice is strong.

THE MANAGEMENT OF CLAY SOILS.

ACCORDING with my thirty years' experience, the true way to conquer these soils and make them profitable is by very high farming—that is, after the under-surface draining, to feed them abundantly with rich cake-fed manure made under cover, and thence at once carried to the land without any intermediate dung-heap; adding, for a great mangel crop some 3 cwts. of Peruvian guano and 1 cwt. of salt. For a full wheat crop after mangel, apply 2 cwts. of guano and 1 cwt. of salt, intermixed before sowing, and applied at seed-time. I once grew 7 qrs. of wheat after heavily manured mangel, and never expect less than 5 qrs. per acre. All this implies that we have plenty of cattle-making manure under cover both summer and winter, for which ample capital must be found. Our red clover is first mowed for hay, then immediately top-dressed with twelve cart-loads of fresh-made rich cake manure direct from the covered yard. When the second growth of clover comes well above this manure, fattening sheep are folded on it, consuming cake, corn, malt culms, &c. The land is then 'saucy' for white wheat, which must not exceed one bushel of seed per acre. After the white wheat is harvested, we take on the same ground a crop of rivetts, and then mangel heavily manured. In 1868, a good wheat year, I thus harvested 8 qrs. per acre of fine white wheat, sold from the machine at once at 63*s*, per qr. ; and on the same ground grew, in 1869, 7¼ qrs. of rivett wheat, followed by 39 tons of mangel. These heavy dressings and large crops are a certain cure for stiff clays, for they diminish greatly the *pro rata* fixed charges of rent, rates, tithes, seed, and manual and horse labour.

Poor farming and small returns on such soils are ruinous. It would be better not to farm at all than do so with insufficient capital. These non-calcareous, glutinous clays, which crack in drying, and are therefore unfit for the ordinary brick-making. They are like bird-lime when wet, and extremely hard when dry. Sheep cannot be folded on them in the wet season. Carting roots, off, and carting manure on, is no easy task at times. These clays soon run into a mud condition if water stagnates in them; therefore the most important conditions are under and surface drainage, to plough them before winter, taking especial care, even where under-drained, to keep open furrows and water furrows to withdraw water quickly from the seed-bed, and thus preserve as much as possible, its friability. I knew of some large farms in Essex on these clays, which caused heavy loss to farmers who came from a friable or drier district, and who have laid these lands on the flat, and have thus lost their crops in the mud. I know of such farms, even where under-drained and fairly manured, which have failed for want of open surface furrows, especially where deeply steam-ploughed. A farmer, used to a friable dry soil, workable at almost any time, feels perplexed and annoyed on our stiff clays, where horses or steam ploughs cannot go on the wet land for many days until a propitious change. A wet, frostless winter on such soils causes much idle time for men and horses.

Frost (when we can get it) is the grand and uncostly pulverizer of such soils. I once ploughed part of a field when wet for oats ; frost did not come, so the furrow slices dried as hard as cast iron, and were too obdurate even for my Crosskill, so as rain did not come in time we could not sow our oats until too late to get a crop. Strangers could hardly realize such a condition of soil, and should, therefore, consult local practice. Where steam ploughed in autumn on the flat, local farmers immediately draw out open furrows (at a distance of 7 feet in Essex) by the ordinary horse plough, to keep the land dry during winter, so that, for spring sowing it would only require broadsharing or scarifying. Spring ploughing for root crops in these dense soils is a very hazardous affair now. Farmers are finding out that very deep cultivation with the powerful steam plough is a costly mistake. Too much of the bad subsoil gets mixed with the seed-bed. Steam ploughs are now much used in this neighbourhood, but at diminished depths. These dense clays are unsuited for permanent pasture, but grow fine crops of red or white clover, winter tares, and especially mangel wurzel. The climate is too dry for swedes. Cabbages do well. Winter wheat and Tartar oats thrive, but the land is too stiff for barley. No rye-grass is sown with the clover, which is only taken for one year, and followed by winter wheat, which has an abundance of straw. The land for mangel should be very heavily manured with covered yard manure, ploughed under before winter, and only scarified in the spring receiving an addition of 3 cwts. of Peruvian guano and 1 cwt. of salt. Very heavy crops of mangel (30 to 40 tons per acre) may thus be grown on these soils, while swedes would generally be mildewed and a failure.

Covered and enclosed yards are the great panacea for such soils. In these cattle should be fed winter and summer as manure-makers on cut up green food or pulped roots, mixed with plenty of cake, corn &c. Horses should also have cut up and prepared food. Sheep do well in winter under cover, either on straw or sparred floors. They do not get foot-rot in covered yards, although they do so in uncovered yards. These stiff soils are impracticable for sheep in winter. I fatten them very successfully under cover, but they require less warmth than cattle. The great advantage of covered yards is economy of straw, preservation of manure, which should go direct to the field, 10 loads of it being equal to 15 of dung heap or open yard manure. Thus there is a great saving of horse and manual labour. My neighbours are at length availing of them. With proper ventilation, and a slight daily littering, animals in these yards are especially healthy. I have experienced this for fully 30 yards. By covered yards these heavy lands become meat-makers, which I consider most important. I make meat to get manure, and thus obtain maximum corn and other crops. Such arable farms require much tenant capital—£15 to £20 per acre would not be too much, to produce the most profitable results. It is a great mistake to take such farms with only £8 to £10 per acre. The amount invested in live stock alone should be at least £6 per acre ; much of it fed on imported food. It is surprising how far a good green or root crop will go if passed through the cutter or pulper. It pays better than turning out and roaming at large. Iron hurdles on wheels for sheep pay well. In conclusion both I and my bailiff are fully convinced that this farm could not be profitable at present prices with uncovered yards, the roaming at large of animals, and the undrained and little fields of ancient custom. I feel for those who still have to farm under such adverse conditions. The extra £1 of rent for all modern improvments is the key to profit.—*J. J. Mechi.*

THE GUTTA-PRODUCING PLANTS OF THE MALAY PENINSULA.

IN an appendix to a report of an expedition to Perak, recently made by Mr. Murton, the superintendent of the Botanical Gardens, Singapore, a good deal of information is given regarding the sources of the different kinds of gutta produced in the Malay Peninsula. Five varieties are enumerated, and their respective values in Perak and Salangor given as follows :

		Price per picul. In Perak.	In Salangor.
1.	Gutta-soosoo	... 50 to 52 dols.	not known.
2.	Gutta-taban	... 45 „ 50 „	50 dols.
3.	Gutta-rambong	... 32 „ 35 „	not known.
4.	Gutta-singgarip	... 17 „ 20 „	20 dols.
5.	Gutta-putih-sundek	... 15 „ 30 „	15 „

Of the first—gutta-soosoo—Mr. Murton was unable to obtain any samples of the tree producing it, and the only information he could gather concerning it was that the tree is entirely destroyed, except in the interior of Perak ; that the gutta is firmer in texture than gutta-taban, and contains a little oil. This must not be confounded with the gutta-soosoo of Borneo, which is a caoutchouc or rubber.

The second, or gutta-taban, is the gutta percha of commerce, and the product of a tree described so far back as 1837, by Sir William Hooker, under the name of *Isonandra gutta*, but now known to botanists as *Dichopsis gutta*, Bth. It appears that, in Perak, there are two sorts alike in foliage and general appearance, and differing only in the colour of the flowers, one being white and the other red. They are known to the Malays by the names of *Ngiato putih* and *Ngiato merah*, but the products of both trees are called gutta-taban. *Dichopsis gutta* is most abundant on Gunongs Meeru and Sayong, and Bujong, Malacca. A few large trees still exist on Gunong Babo and the Thaipeng range. Small plants, from one to eight feet, are abundant on the granite formations in Perak up to 3,500 feet elevation.

To procure the milk, the tree is cut down at five or six feet from the ground, and the top cut off immediately, when it becomes too small for ringing. This, the native say, causes the tree to yield a much larger quantity. The bark is then ringed with small knives called "golos" at intervals of from five to fifteen inches. The milk continues, to flow for about an hour, and is collected in vessels made of palm leaves or cocoanut shells, and then boiled for about an hour, otherwise it becomes brittle and useless. Regarding the quantity of gutta each tree is capable of producing, no trustworthy information seems to have been obtained. One of the principal merchants of Perak informed a member of the expedition that a large tree will yield forty catties of gutta, but Mr. Murton regards this as an exaggeration, for from numerous inquiries among the men in the jungles he was told that from five to fifteen catties is about the average quantity obtained, and never more than twenty catties. No particular season seems to be recognised in Perak for collecting the gutta, and Mr. Murton was unable to glean any information as to, whether or not the trees yield more in one season than in another. He considers, however, that in the wet season

the gutta contains more water, and consequently would require more boiling to drive it off. It is stated that from Klang 83 piculs, 88 catties were exported from January to November 1877; so that it is probable over 700 trees were destroyed to furnish that quantity. The gutta is generally, if not always, exported in the shape of oblong balls, with a loop at the upper end, through which a piece of rattan is put to facilitate its being carried through the jungles. These balls vary considerably in weight, from 10 to 20 catties is about the average. They are of a greyish-white colour, with a slightly reddish tint inside. The colour, however, varies according to the quantity of bark and other impurities mixed with it; sometimes it is of a bright umber brown.

For the cultivation of *Dichopsis gutta*, it is recommended that plants not more than a foot high should be procured from the jungles; it is necessary to lift them very carefully, as they have long tap roots which are liable to be broken or injured, in which case the plants, even if they survive, take a long time to recover.

The third kind of gutta, namely, gutta-rambong, is described as being more of the nature of caoutchouc, or india-rubber. Mr. Murton did not find the tree producing it and he was informed by the Malays that it was only to be met with in the interior of Perak, and on the Patane side of the Peninsula. These people describe the tree as having large roots above ground, and large, bright-green leaves, with red tips to the branches. The milk is obtained from these large roots, which are tapped ten or twelve times a year, a picul being sometimes taken from a large tree; the usual yield, however, is said to be about half a picul. This rubber is said to require no preparation for market. It has the appearance of long strings irregularly welded together; the best quality has a gum-like appearance, is very firm in texture, and of a reddish-brown colour; the inferior qualities have a large admixture of bark, &c. and are much drier, without the gum-like consistency of the better qualities. The caoutchouc from Perak has much the same appearance as Assam rubber, and Mr. Murton considers there is but little doubt that it is produced by the same tree *Ficus elastica*, description given by the Malays agreeing closely with that of the above-named plant, the red points to the branches being probably the conspicuous red stipules which envelope the young leaves. From the fact that young plants have been promised to the Singapore Gardens, it is to be hoped that ere long the origin of gutta-rambong will be definitely settled.

Another caoutchouc or India-rubber is gutta-singgarip. This agrees very closely in texture, appearance, and in the mode of operation with the gutta-soosoo of Borneo, and Mr. Murton says that an experienced authority, who had spent some time among the gutta-soosoo collectors in Borneo, assured him that they are one and the same product. The plant producing it is a large woody climber, with stems about six or eight inches in diameter, but often much less. There are two varieties; one with very dark coloured outer bark and lighter coloured warts, and red inner bark; and the other with outer bark light cork-coloured, with longitudinal channels, and the inner bark light yellow. The foliage of both plants are described as being very similar to each other, but the fruits differ in form, one being apple-shaped and the other pear-shaped. The fruits of both forms are edible, and are readily sought after by the Malays. The plants seem to be species of *Willoughbia*, belonging to the natural order, *Apocynaceæ*. The gutta from the dark-barked variety is considered the best. The long, scandent stems are often cut down to procure the milk, but it is not absolutely necessary to do so, except to render the operation of collecting the gutta easier. The stem is generally ringed at intervals of 10 to 12 inches, and the milk allowed to run into vessels made of palm or other leaves, cocoanut shells, or anything available for the purpose; it continues to flow for some time, but after flowing for ten minutes it gets very watery and thin. One plant will yield from five to ten catties of the coagulated caoutchouc. When raw it has the appearance of sour milk, and to coagulate it the natives add salt or salt water. When freshly coagulated it is quite white, but gradually changes to a darker colour. It retains its white colour inside, and upon cutting it is found to be porous, the pores or cells containing water and salt, which have become enclosed during coagulation. In texture it is soft, very spongy, and very wet. From January to November, 1877, 57 piculs 45 catties of this rubber were exported from Klang alone. Gutta-putih or gutta-sundek, is the produce of a species of *Dichopsis* the leaves of which differ from of *D. gutta* in being much shorter, broader and more ovate in general outline. The gutta is obtained and prepared in the same manner as gutta-taban and trees are frequently met with on the Sayong and Meeru ranges. Of this variety 484 piculs 56 catties were exported from Klang alone, from January to November, 1877. It is much whiter and more spongy than gutta-taban, and is worth only 15 dols. per picul as against 50 dols. for gutta-taban. In concluding this interesting report, Mr. Murton says:—"When crossing the Meeru range from Kinta to Kwalla Kangsa, I cut off some leafy branches from a tree which had been felled and ringed a few days before. These leaves were beautifully yellow on the lower surface caused by small peltate scales, and not pilose hairs, as in the *Isonandras* (*Dichopsis*), but on making inquiries from men about Sayong, they pronounced them to be foliage of some non-gutta yielding tree, which is certainly wrong, as I saw the dry gutta adhering to the bark where it had been ringed. A kind of gutta, called gutta-jalutong, is often used in Perak for mixing with guttas taban and putih, thus rendering them very brittle, but I have not seen the gutta, nor the tree producing it. *Isonandra Motleyana* is said to yield a gum which, in Java and Sumatra, is known as gutta-kollan, and is used only for adulterating purposes. Various species of fig (*Ficus*) yield large quantities of milk, which in Perak is known as gutta-barong, as the only use to which it is put is for bird-catching."

From the foregoing remarks, it will be seen that there is a great deal yet to be learnt about the sources of those valuable plants and trees yielding elastic gums, and it is to be hoped that, with an extended knowledge of the plants themselves, increased supplies may also find their way into commerce.

INDIAN SUGAR AT THE PARIS EXHIBITION.

ANALYSES made in the first fortnight of March on ripe cane Average samples of chips from the cutting of whole bundles, weighing from 100 to 120 lbs., taken for analysis.

CARDAMOM CULTIVATION.

A VERY interesting paper has been written by Mr. Dickenson, Assistant Conservator of Forests, on the cardamom cultivation in Coorg, a subject which is not much known in this part of the country. This plant is indigenous in Coorg and the western coast, and has long been an article of commerce with foreign countries. Some years ago two English planters tried the experiment of cardamom plantations, but they found that the produce was so great in its natural state, that it was impossible to compete with those who were able to get it for nothing, or next to nothing. It is not likely that the experiment will be repeated. It is only during a portion of the year, namely from November to April, that these forests can be examined. Mr. Dickenson was only able to go through a portion of the forest during the time he was employed, but the part of the country that he took in hand seems to have been gone through thoroughly. These forests are situated, for the most part, on the western slopes of the ghat, there are very few on the inland side, and those few are situated to the north-west of Nalknad, together with a few locks in Kadyatond. Almost the whole of the western slopes are wooded except the upper part, where are belts varying in height from 500 to 1,500 feet, which are generally bare of forest or grass of any kind. The slopes are generally very steep, and the ground is covered with decaying leaves, the trees are numerous and grow to a great hight. Between the trees the ground is covered with leaves so that the sun rarely gets to it. The height and appearance of the cardamom vary in different parts of Coorg. Where the ground is cleared for cardamom cultivation, many kinds of plants and weed spring up at the same time as the cardamom plant, the seeds of which have been lying dormant in the ground with that of the cardamom plants. The cardamom plots are formed by felling two or three trees, the Coorgs being pretty well acquainted with the places where cardamoms are likely to spring up, after which the plant is left to grow, the only operation being to weed ; this is done at the annual period of picking the crops in the neighbouring clearings. After four or five years of crop, one or two more trees are felled, probably, because the branches of the surrounding trees have grown over the cleared area, and it is necessary to again let in the requisite amount of light. The plant begins to lessen in crop at about ten years, and the clearing is abandoned at about fifteen to twenty years, when the forest again grows up. An old garden seldom exceeds an acre.

Mr. Dickenson thinks that there is little fear of the forests deteriorating from the method of cultivation now in force, and he says, that it is a waste to let the land lie idle for years. It is thought that it would not be well to allow the wind to penetrate into the forest. With regard to the quantity of land that ought to be cultivated, the report before us says :—

"The Coorgs understand very well the danger of "killing the goose that lays the golden egg," the consequence of felling any large extent of forest for cardamom cultivation ; but to be on the safe side and in case the renters be tempted to open out the forest too much by another such a rise in the prices in cardamoms as occurred a few years ago, it would be a good plan to institute a rule by which only one cardamom clearing should be made to so many acres, say 1 to 30-40, these are only guess figures, and very likely the proportion might be safely increased. They might be easily fixed by measuring areas at present under safe cultivation. Another good check would be to fix the maximum area to which a clearing may be opened. I beg to point out however, that the conclusion I have at present come to from an inspection of a part of the ghâts is liable to be modified on an examination of the rest. But I have no hesitation in saying, that with the present low prices obtainable for cardamoms, there is no immediate danger whatever to be apprehended."

The clearing of forest unless the land is immediately taken up is deprecated, for when the land is cleared, if it is not at once cultivated, the forest does not re-assert itself, but a low scrub grows up which often takes fire in the hot season and which extends to the forest beyond. The consequence of the clearing of the forest is the diminution of the water supply of the district, and it ought to be the object of the Government to prevent as much as possible this being done. More especially, should the forests on the slopes of the ghâts, and near the sources of rivers be conserved. The Coorgs, we are told, are imitating their European brethren in clearing the forest, the high price of coffee tempting them to invest in this industry rather than allow the forest to stand as it has done for ages. It is likely that the subject of the depletion of trees will be brought under discussion at the assembly of the Commissioners to enquire into the cause of famine, and it is one that requires their most earnest attention.

THE INFLUENCE OF TREES ON RAINFALL.

DR. EDWARD BALFOUR, the late head of the Madras Medical Department, has furnished the India Office with a memorandum on the "Influence of Trees in India," which memorandum is being distributed in India for the benefit of the present generation of administrators. Dr. Balfour, tells us that he wrote and printed a paper on the above subject so long ago as 1840, and that in 1847 the Court of Directors called for information from India on the question whether the rainfall and productiveness of the soil were known to be influenced by trees. It was only from the Madras Presidency that any information was furnished to the India Office. It is interesting to note what the Madras Collectors had to say on this subject in 1848, or thirty years ago. Mr. Blane, Collector of Canara, denounced the way in which the forests were being destroyed, and recommended Government to preserve all forests which were not private property. Mr. H. Forbes thought there had been no appreciable decrease in rainfall, but that the water ran off more rapidly after forest clearances. Mr. Connolly, of Malabar, furnished the rainfall for 38 years, and showed that the amount had not decreased, though the clearance of jungle had been great. In North Arcot, Mr. Binning was informed that "the rains for the last 20 years or more, had not been so copious or regular in that district as in former days, and that, of late years, the jungles and supplies of water had gradually diminished." The people of Salem told Mr. Lockhart that "when the streams from the hills of Oollymally, Tullamally, and Ninamally were covered with jungles, the water was continually running, but after the jungles were removed and the lands were converted into nunjah and to totekal fields by means of reservoirs, wells and tanks, these natural streams had been affected." The Collector of Bellary noted the fact that Ramandroog Hills, 3,000 feet above sea level, was often surrounded with dense mist, when the plains below were dry and parched. Dr. Balfour, who first visited Ramandroog in 1845, and again in 1865, noticed on the latter visit, the great diminution that had occurred in the trees on its edge and sides. Dr. Balfour declares the railways have had much to do with our forest and jungle clearances. The Committee appointed by the British Association in 1851, consisting of Dr. Cleghorn, Dr. Forbes Royle, Captains Baird Smith and Richard Strachey, did much

to rouse Government to the necessity of protecting forests and planting trees. Among the writers who did good service in the establishment of Forest Departments, Dr. Balfour mentions Mr. Justice Innes, who issued three pamphlets on the subject, and urged the importance of planting the hills with trees wherever a tree would grow. We agree with Dr. Balfour that the public should be furnished with a comprehensive *resumé* of what the Forest Departments have done, with a view to determining whether the labours of the departments may not be profitably extended. The conclusion Dr Balfour comes to, after many years consideration of the subject is that [illegible] the present century, the rainfall has not diminished nor has the quantity annually falling become more uncertain [illegible] man, partly ignorant and wholly reckless, has denuded the soil of its trees and shrubs, and bared the surface to the sun's rays, thus depriving the country its conservative agents, and making the extremes of floods and droughts of more frequent occurence, and more severe.'

CULTURE AND USES OF THE CASSAVA.

THIS plant is a native of tropical America, where it has always formed one of the chief food resources of the population; indeed, it stands in nearly the same place in those countries that the potato holds in more temperate regions.

There are two distinct species, the sweet and the bitter; the fresh juice of the latter is a deadly poison, but [illegible] in the sweet kind. Boiling [illegible] to destroy the poisonous quality in the bitter kind, but that is not [illegible] depended on. The usual practice in the West Indies is to press [illegible] the juice and [illegible] it in the sun, or more commonly [illegible] constructed [illegible] the purpose, when thoroughly dry [illegible] perfect [illegible]

It is probable that this plant was introduced into Ceylon in the time of the Portuguese domination; it was certainly here in the time of the Dutch, and though it has never been much used, it has [illegible] Government [illegible] cultivation [illegible] attention to the growing of this plant, and for some years the cultivation [illegible] gradually extend [illegible] cocoanuts [illegible]

The usual mode of proceeding [illegible] the dry season and give [illegible] usual [illegible] kurakkan crop. Pieces of cassava stick [illegible] three feet [illegible] holes [illegible] distance when the first rain of the season has softened the soil sufficiently for the purpose. Over this the kurakkan is sown, when the monsoon rains have sufficiently saturated the ground. Four months afterwards the kurakkan is harvested, the surface weeded, and a slip of sweet potato vine stuck in here and there, and nothing more is required for twelve months, or rather nothing more is done except to guard more or less successfully against the depredations of cattle and wild pigs. The practice is to sell the crop on the ground at prices varying from two to six pice per bushel, the purchasers digging for themselves.

It would probably be a more profitable system to grow each crop by itself in succession, but the natives have their own ways and will neither learn nor forget anything. In one instance another plan has been tried, with what success remains to be seen. The roots of all jungle plants that survived the running fire were either dug out or their vitality otherwise destroyed. The cassava was planted in lines at five feet apart, the ground was regularly weeded till the plants met and shaded it and kept down all other growth. The estimated crop of this land is ten tons of roots per acre, and the time twelve months.

The fresh roots boiled eat very much like potatoes, both in taste and consistency, and are in this state wholesome food for man and all kinds of domestic animals. Pigs and cattle eat the raw-fresh roots greedily, and thrive on them. The dried roots moistened with water are good food for pigs and cattle, and ground and sifted, it makes excellent cakes and puddings; ground without sifting and moistened, poultry prefer it to grain. The fresh roots reduced to a pulp washed with plenty of clean cold water, and the fibre separated by a sieve, a pure starch will settle to the bottom of the vessel used, which rolled into pellets while moist, dried in the sun, and passed rapidly over heated metal plates, becomes the tapioca of commerce, an article which most people are acquainted with, as sold in the apothecaries' shops at a price too high for common use.

It is believed that the fresh cassava roots would pay the producer at 24s. per ton on the spot. It takes four pounds of fresh roots to make one dried, and the labour per cwt. will be at least 75 cents so that the corresponding price for the dried article would be 6s. per cwt. What pure starch, either in powder or the form of tapioca, could be produced for is beyond the present knowledge of the writer hereof, but with proper machinery it could probably be done to pay at from £6 to £8 per ton. The price in the London docks used to be 1½d. to 2½d. per lb.

As the roots soon [illegible] after two days; if, the[illegible] as an article of either [illegible] the dry state, and as th[illegible] when it can be depend[illegible] weeks in the year), per[illegible] cider mill to reduce [illegible] drying house, where art[illegible] thus doing in one day w[illegible] weather, and in wet [illegible]

Ceylon.

20 The proportion in [illegible] the mangels anal[illegible] table:— [illegible] a public, to all comers [illegible] second class the [illegible] Agriculture only; [illegible] ryots or their

NITROGENOU[illegible]

EVERY farmer who is i[illegible] feeding materials o[illegible] minoids,' or 'flesh former[illegible] of bodies similar in compos[illegible] the class of bodies bearing this name [illegible] highest importance. Animal tissues are largely made up of albuminoids; indeed, lean muscle almost entirely consists of these substances, which in consequence have received the name of flesh-formers. [illegible] albuminoids essential constituents of the animal body [illegible] present in all forms of vegetable growth, and without albuminoids no increase of plant tissue is possible. It is in the form of vegetable [illegible] that animals receive all the albuminoids afterwards stored up in their own bodies.

It is evident from [illegible] the [illegible] of albuminoids contained in [illegible] great practical importance, the feeding value of a food will in fact depend a good deal on the quantity of albuminoids present. [illegible] great importance of albuminoids that a statement of their quantity is to be found in every analysis of feeding materials.

Unfortunately chemists have not till quite recently possessed any accurate and speedy method of ascertaining the quantity of albuminoids [illegible] sample of food. They have consequently been forced to determine a single constituent of the albuminoids—the nitrogen, and to calculate from the amount of nitrogen the quantity of albuminoids present. Now as all albuminoids contain a constant, and nearly uniform percentage of nitrogen it is perfectly safe and accurate to calculate from the amount of nitrogen in food the amount of albuminoids which it contains [illegible] substance containing nitrogen is present. In the case of [illegible] and of most kinds of seeds, nearly the whole of the nitrogen present really exists in the form of albuminoids in such cases the calculations of the chemists are fairly accurate, and the albuminoids stated in his report are with slight difference, actually present in the food. When, however we turn to succulent foods such as roots or green fodder, the analyst's calculations are entirely at fault. Here, as in other cases, he is accustomed to multiply the nitrogen present by 6·25, and to consider the product thus obtained as the quantity of albuminoids present in the roots or hay. The conclusion is, however, erroneous, as vegetable foods of this class contain several nitrogenous bodies besides albuminoids; to reckon the whole of the nitrogen as albuminoids will, therefore, greatly exaggerate the amount of albuminoids really present.

It is only within the last few years that we have obtained any accurate knowledge of the various nitrogenous bodies present in roots. Previously to these recent investigations, it was assumed that the whole, of the nitrogen existed as albuminoids. The investigations in question have been carried out chiefly by E. Schulze, though with him other chemists have been from time to time associated. The roots examined have been chiefly mangel wurzel, and more recently potatoes. We will endeavour to give some account of the results arrived at.

In 1867 Schulze called attention to the large amount of nitrates contained in many roots. He determined the amount of nitrogen present as nitrates in mangels, sugar-beet, turnips, and carrots. The amount of nitrogen thus combined varied from 1 to 31 per cent. of the total nitrogen present. The largest quantity of nitrates was found in mangel wurzel. Besides nitrates Schulze found that the sap contained a small quantity of ammonia, varying in 14 analyses from 0·006[illegible] to 0·0285 per cent. of the fresh sap.

In 1875 Schulze published a far more complete investigation this time confined to mangels. He determined with great care the amount both of soluble and insoluble albuminoids, the quantity of nitrates, and also of ammonia. But, besides these ingredients, he now for the first time ascertained that mangel contain a large amount of soluble amides.* The exact nature of those amides he did not then ascertain, but merely the quantity of nitrogen which existed in this form of combination. He further showed that mangel contains another nitrogenous body—betaine, which Scheibler had already shown to exist in sugar-beet.

In 1877 Schulze published a further series of results, obtained with mangels of another season. This investigation included the change which takes place in the second year's growth of the root, when flower and seed are produced. In this investigation he ascertained the nature of the amide [illegible] abundant in mangels; he found it to be glutamin and associated with it a small quantity of another amide—asparagin.

* An amide is a body containing nitrogen in the form of amidogen—NH_2.

... with these various nitrogenous bodies occurred in ... by Schulze will be seen from the following

Analysis of ... for sug...

	1,000 parts of fresh mangel contained.	
	Roots of 1874.	Roots of 1875.
Albuminoids, insoluble	6·950	1·028
" soluble	2·306	1·413
Glutamin and asparagin	4·060	4·425
Betaine	1·359	0·226
Nitric acid	3·863	2·483
Ammonia	0·080	0·085

With the exception of the insoluble albuminoids, the whole of these nitrogenous bodies exist in solution in the sap of the root. The manner in which the nitrogen was distributed among these various bodies will be seen more clearly from the next table, where the total nitrogen in each mangel is taken as 100, and the distribution of this among the various nitrogenous bodies is shown. The mangels of 1874 contained 0·2400 per cent. of total nitrogen, those of 1875 contained 0 1979 per cent.

	Nitrogen of each constituent in 100 of total nitrogen.	
	Roots of 1874.	Roots of 1875.
Albuminoids, insoluble	6 33	8·29
" soluble	15·38	11·42
Glutamin and asparagin	32·15	42 80
Betaine	6·71	1·36
Nitric acid	36·28	32·54
Ammonia	2·75	3 59
Total nitrogen	100·00	100·00

The quantity of nitrogen existing as albuminoids is seen to be comparatively small; in the first mangels only 21·71 per cent. of the nitrogen present is in the state of albuminoids, in the second mangels 19·71 per cent. When analysing other mangels less rich in nitrogen, Schulze found a somewhat higher proportion of the nitrogen in the state of albuminoids; the proportion was in one case 29·79, and in another 37·92 per cent. of the total nitrogen present. It is plain that if these roots had been analysed in the usual way, and the whole of the nitrogen calculated as albuminoids the quantity attributed to the mangels would have been three to five times in excess of the truth.

Nitrates are apparently a very variable ingredient of mangels, sometimes reaching a very large proportion. In the analyses now referred to the nitrogen as nitrates formed from 9·46 to 44·06 per cent. of the total nitrogen.

The nitrogen existing as amides is in every case a large proportion of the whole. The principal amide-glutamin was not isolated by Schulze, he only obtained the acid (glutamic acid) which is formed by the splitting up of the amide. He obtained in the same way asparatic acid, formed by the splitting up of asparagin. These acids are proved by his investigation to have existed in the original sap as amides. Both glutamic and aspartic acids are known as products of the decomposition of albuminoids, and are thus plainly related to them.

Betaine is present in small and variable quantity; it diminishes as the root approaches maturity. Scheibler found 0·234 per cent. in the sap of sugar-beet on July 1; this quantity had fallen to 0·084 per cent. by October 1. Betaine is, very curiously, identical with a substance known to exist in the brain, and called by its discoverer oxyneurin.

We have said enough to show the complicated character of the nitrogenous ingredients of roots, and the fallacy of assuming that the whole of the nitrogen present is in the form of flesh-formers. In a second paper we hope to describe the results which Schulze has obtained with potatoes, and his investigation on the part taken by the amides and nitrates in plant nutrition.—R. W. in *Agricultural Gazette*.

FIELD EXPERIMENTS WITH POTATOES.

We are indebted to Mr. Wilson, Chapelhill, Berwickshire, for the following very interesting report of experiments conducted by him last season:—

During the season I have made some experiments on Victoria potatoes, which may prove interesting to some of your readers, if you will allow me space to give the results. On March 15th I planted a field partly with whole potatoes of second size as usually dressed for seed, and partly with cut sets, *viz*, potatoes of medium size cut in two, lengthways, no potato being cut into more than two sets. The portion planted with cut sets braided about ten days earlier than the whole, came away more regularly, and in fact had a more luxuriant appearance throughout the season, from which I expected they would prove the heavier crop. This I attribute to the cutting of the potato causing earlier decay, and consequently more rapid growth; and this is borne out by the fact that in lifting the crop this week the whole sets are many of them intact, while not a vestige of the cut remains. So marked was the difference throughout the summer, that many thought the whole sets had been inferior seed. They were, however, the same seed, and only separated the day before they were planted. The crop lifted as follows (per imperial acre):—

	Tons.	Cwts.	Qrs.	Lbs.
Whole Seed	10	18	2	18
Cut seed	9	1	1	3
In favour of whole seed	1	17	1	18

Whole Seed.		Cut Seed.	
Ware ...	84·622	Ware ...	73·411
Seconds...	11·062	Seconds...	18·573
Chats ...	4·316	Chats ...	8·016

The victoria bearing such a heavy crop of apples, I formed the opinion that the maturity of these must exhaust the strength of the plant, which ought to go to form tubers, and this induced me to cut the blooms off a few drills to prevent them forming apples. This I did when they were in full bloom, and again ten days later, when they showed a tendency to bloom a second time. The consequence was they continued growing, and became much stronger in the haulm than other parts of the field, and were so observable up to the time of lifting as to attract the attention of casual passers by. The following is the result:—

	Tons.	Cwts.	Qrs.	Lbs.
Bloom cut off produce	10	8	0	14
" left on "	9	1	1	24
In favour of bloom cut off	1	6	2	18

Bloom cut off		Bloom left on.	
Ware ...	87·502	Ware ...	78·824
Seconds...	9·706	Seconds...	15·132
Chats ...	2·792	Chats ...	6·044

These are the *average* results of six separate experiments in different parts of the field; and in every instance the result was decidedly in favour of the cut bloom; indeed, it was quite apparent to the eye, without recourse to the steelyard, that the crop was superior both in quantity and quality. The drills tested were immediately adjoining, in some instances one on each side of that from which the blooms had been cut. I hope this may induce others to try further experiment in the same directions next season.

IMPROVEMENT IN NATIVE AGRICULTURE.

A CORRESPONDENT signing himself MUKKUKANNADI writes to a Madras paper:—

"From your issue of Monday, I see that the late Colonel Vertue recommends, as a partial remedy for denudation of forests, that villagers should be induced to plant trees. This might easily be done, if they only knew where to plant them, as every one at all acquainted with them knows how readily they adopt any simple means of improving their cultivation, if the advantages to be derived are clearly demonstrated to them. Now they are always eager to obtain leaves of trees (to burn down into manure, or simply to place on the land, there to rot), and may be seen out in the open country sweeping together the leaves of avenue trees, &c.; and one constantly sees in their fields heaps of manure, consisting chiefly of the stalks of plants, leaves, &c., carefully placed ready to be ploughed in or spread over the land. They are also willing to pay for loppings of avenue and other Government trees, to be used as firewood. In fact on the west coast (and probably on the east coast also,) if allowed to do so, they would strip avenue trees of every leaf they have, for manure, or even cut down every tree for firewood. I think we may assume, then, that if assured of getting the leaves and loppings, they would willingly plant any number of trees near their holdings, the only trouble required being to put in a bough (which is quite sufficient, though not perhaps the best way of proceeding), and perhaps to water the saplings thus obtained, now and then. Now for this, there ought to be sufficient room in every village; because, theoretically, 30 per cent. of the land of every village ought to be reserved for communal purposes. And further, if such rough and ready saplings were planted at regular intervals on the boundary of this land, left uncultivated for common use, it would check the suicidal practice, almost universal I believe, of ryots continually encroaching on this 30 per cent., and would drive them back from absorbing the pasture land, to cultivating more highly the land they have. Cases are continually cropping up in which ryots are found cultivating parts of such waste land; on investigation it appears that the piece in question is almost surrounded by lands already cultivated and entered in *puttahs*, and so is less eligible for communal purposes, as not being easily accessible. So, in a weak moment, the division officer allows it also to be entered in the cultivator's *puttah*, and once entered in a *puttah*, it is not interfered

with. There are few villages where the orthodox 30 per cent, is reserved, and as a consequence the pasture land of the village decreases in extent yearly; eventually, perhaps, it is so hemmed in by cultivated lands (the village path to it also being by this time absorbed in some one's holding) as to be inaccessible, and the cattle of the village have to be driven farther afield which gives extra facilities for cattle thefts. So much for planting and pasturage.

"There is one means of supplying the ryots with manure which is not nearly so well developed as it ought to be, and that is by managing properly the sweepings, &c., of towns. The paddy and grass which come from the soil, are taken to the town and there absorbed as food; but nothing is taken back to replace them, while the animal and vegetable manure produced in the country itself does not count, as it does its own share of exhausting the soil, (the vegetable part having come straight from the soil, and the animal part being derived from grass.) Looking then at the enormous amount of fertilising elements annually sunk in food, without any return whatever to the soil; what can we expect but gradual impoverishment of the soil? The natural corrective, *i.e.*, the alluvial matter which washes down from the hills, must apparently diminish in quantity, year by year, unless the supply is inexhaustible, which there is no reason to believe; and as this corrective is less effectual every year, and the population, the exhausting element, increases every year, the process of impoverishment must go on with ever increasing rapidity. I think the action of animal life in connection with food may be described as follows. Leaving fish out of the reckoning, as they are so to speak on a separate establishment, we may assume that all food for man or beast comes from the soil, directly or indirectly; corn and vegetables and grass being an instance of the former, and flesh of sorts, an instance of the latter. All this comes from the soil. Now where does it go to? What becomes of it? It will be admitted that after being taken as food, it is changed either (1) into part of the animal's body, or (2) into something which passes off at daily or lesser intervals, or (3) into gas (such as carbonic acid gas, &c.) which passes off as breath. Part No. I. will, unless the animal be human, probably return to the soil when the animal dies; but if it be a man, the loss to agriculture at its death may be two-fold, *i.e*, (*a*) the body itself will not return to the soil, and (*b*) in the case of Hindoos, a large quantity of fuel (generally about Rs. 100 worth) will be lost, and its place have to be supplied by cowdung which ought to go into the soil. The loss to agriculture by the human body not being utilised, has been much dwelt on by scientific men and others, especially in connection with the question of cremation in Europe. It is, however, perhaps hardly to be expected that human feeling on this point will ever yield to arguments of utility, but all the more need on that account to guard carefully against waste in other ways. Part No. 3 (the gas) is largely utilised by plants, and is perhaps almost essential to their existence. But the most important item is no doubt No. 2; for that which a man casts off in a lifetime is much greater in quantity than what is left when he is dead. If then the whole excreta of the town of every sort, sweepings, &c., were utilised as manure, the impoverishing process would be greatly checked, and we might here in India last out very well till we can afford to import artificial manures. One question, however, requires consideration; that is, whether the present cheap supervision of Municipalities really pays. How can the President or Vice-President of a Mofusil Municipality find time and energy to work out the problem of utilizing all the off scourings of the town? Would it not be better, instead of making the whole thing a burden to some official, or some half-hearted unpaid private individual, to employ a paid Vice-President on a substantial salary, say of Rs. 200 or Rs. 300 a month? Probably the saving by efficient supervision would almost pay the extra cost, to say nothing of the benefit to health and agriculture. There is another point one would like to mention, if this letter is not already too long, and that is that it might be a good thing if steps were taken to provide agricultural literature for the benefit of non-professional men who are in the way of teaching ryots to do better, if they only knew anything of the subject themselves. Could not Mr. Robertson, or some other practical man, bring out a hand-book on agriculture (with special reference to Indian acquirements,) if necessary in monthly parts? Probably two hundred subscribers would be enough to pay expenses, and considering the number of revenue officials, there ought not to be any difficulty in securing that number."

PLOUGHING COMPETITION AT SYDAPET.

A HIGHLY interesting spectacle in connection with educational progress in this Presidency was witnessed at the Government Experimental Farm at Sydapet. The annual ploughing competition came off and attracted a pretty good number of visitors, including the Hon'ble W. Hudleston, Mr. Justice Kernan, and Colonel Macdonald. The public were thus afforded an opportunity of judging how far Mr. Robinson's efforts to introduce and render popular an improved method of ploughing among the natives of the country have succeeded, and also of contrasting the working of an English plough with that of the rude implement used by the agriculturists of India. Prizes at the competition were offered to three classes of competitors. In the first class the competition was open to the public, to all comers to persons on the farm as well as outsiders; in the second class the competition was restricted to students of the School of Agriculture only; and in the third class the prizes were competed for by ryots or their labourers only.

The following were the prizes awarded :—

CLASS I.

1	A Swedish plough ...	Rs.	25
2	An American " ...	"	20
3	Implements or seeds ...	"	15
4	Do. do. ...	"	10
5	Do. do. ...	"	5

CLASS II.

1	A Swedish plough ...	Rs.	25
2	An American plough ...	"	20
3	Implements, or seeds, or agricultural book ...	"	12½
4	Ditto ...	"	7½

CLASS III.

1	An American plough ...	Rs.	20
2	Money ...	"	10
3	Ditto ...	"	5

The judges in the different classes were :—

Class I.—Mr. L. B. Burrows, Mr. J. H. Garstin, and Mr. J. F. Price.

Class II.—Dr. Cornish, Major Bertie Hobart, and Mr. H. E. Sullivan.

Class III.—Mr. L. A. Campbell and Dr. F. G. Shaw.

A plot of ground containing six hundred square yards was allotted to each competitor, and the judges in awarding the prizes took into account the regularity and straightness of the furrow, the depth, the speed in executing the work, and the general finish of the work. For the competition in class II., there were thirteen students of the school, and they competed in two batches, the seven first getting through their work, and six afterwards. The competitors in this class were apprentice hands who have not received a training for more than three months; yet it was gratifying to find them manifesting considerable skill in working the plough. Some excellent work was shown, and an interesting fact in connection with the competitors in this class is that some of them were graduates of the Indian Universities. It is certainly a great advance in the history of agriculture in this country to find B. A's, who once only aspired to some post under Government, turning their hands to the plough and thus setting an example worthy of imitation by their countrymen. This pleasing result is due in a great measure to Mr. Robertson's untiring efforts to make the subject of agriculture as important as he can in the eyes of the natives of the country. He must at first have experienced very great difficulty in getting the educated youth of the country to consent to take to the plough, but having now so far succeeded, there is no doubt that the good result already achieved will tend to much further advancement. While the competitors in class II. were at work, the competitors in class III. also were engaged in an adjacent field. Here was an opportunity afforded for contrasting the working of the English plough with a native plough. It was easily perceived that the quality and quantity of work that can be turned out by an English plough is immensely superior to that done with a native implement. The English ploughs were easily dragged by the cattle employed, and, taking everything into consideration, there is no doubt that an English plough if substituted for a native plough will be a great saving to the person using it.

The competition in class I. was watched with very great interest. Fourteen competitors in all contended for the prizes offered, eight being ploughmen of the farm, one a student of the Agricultural School, and five outsiders. Those belonging to the farm used the cattle and implements of the farm, and outsiders had to provide their own cattle and ploughs. The ploughmen of the farm showed excellent work, and proved what English ploughs in the hands of trained men might be made to do.—*Madras Times.*

THE ARTESIAN WELLS OF PONDICHERRY.

PONDICHERRY, Dec. 4.

IN passing by the public garden of Pondicherry, you now can see at any time, especially in the evening, a large crowd of people, and you will suppose those Europeans and natives are promenading to admire the greenness of the trees and the variety of the flowers; but on entering the garden, you will be an eye-witness to the present great attraction of Pondicherry. The D. P. W. is at work digging an artesian well by a machine supplied with a complete stock of tools, costing Rs. 3,000 to the French Government. After a few days' trial, the drilling is going on with great success and celerity, and has attained the depth of 90 feet. The merit and honor of so important an enterprise must be given to M. Poulain. In spite of the little encouragement his scheme met with at first, this philanthrophic gentleman, moved by the disasters and mortality caused by the famine in 1877, resolved to devote all his energy to seek for the means of alleviating in future such dreadful horrors. At his own expense he made an experiment at Savana the most important cotton spinning-mill of this town, under his management. Although he used only a few,

imple tools, he obtained water on the 9th of September 1877, after eight months of constant labor, thwarted by several difficulties. Encouraged to dig deeper, when 159 feet (French measure) was reached, he discovered an abundant stream, giving per minute 220 litres (887 pints) of water. This spring is at 33 deg. of the centigrade thermometer, giving 7 deg. at the hydrotimeter, otherwise containing 710,000 of terreous salts. M. Poulain then searched in the compound of another cotton manufactory at Oppalam for a spring of water. After 86 days of easy digging, he found at a depth of 112 feet, a stream more abundant than that of Savanah, giving per minute 450 litres (702 pints) of a limped and slightly ferruginous water, showing 31° centigrade thermometer, and 9° of the hydrotimeter.

After these two successful experiments M. Poulain's ability is admired by every one, not excluding his former opponents. Now several native gentlemen are requesting his aid in the digging of artesian wells in their large fields, and he is just now at work in the village of Archipakum in digging his third artesian well. After the two years of dreadful famine we have just now experienced in the south of India, on account of want of seasonable rain, the success obtained by M. Poulain is of the greatest importance, not only for our little French territory, but also for the immense colony of our English neighbors. By the digging of wells in several places, the crops may be assured even if the clouds give no rain, and therefore the famine with its horrors can be in future removed or considerably reduced.—*Madras Mail.*

THE WHEAT CROP IN FRANCE.

FROM an article published in the *Bulletin des Halles*, it appears that the French wheat crop of this year amounts to 82,500,000 hectolitres, or twenty millions less than an ordinary average crop; this appears to be the general opinion, and the crop is therefore as bad as in 1873. The natural weight this year does not seem to exceed 74 killogrammes per hect., which constitute a further deficit, and reduces the total crop to 61,000,000 quintals (27,110,000 qrs.) Concerning the probable requirements and of the resources various countries during the present season, the *Bulletin des Halles* gives the following figures:—

	Imports required. Qrs.	Presumed surplus for export.
France	6,000,000	—
Russia	—	6,200,000
Italy	1,080,000	—
Great Britain	12,070,000	—
Austro-Hungary	—	2,250,000
Belgium	515,000	—
Portugal	175,000	—
Holland	620,000	—
Denmark	—	175,000
Sweeden	70,000	—
Switzerland	1,200,000	—
Norway	103,000	—
United States	—	13,800,000
Algeria	175,000	—
Sundries, including India	—	700,000
Total	22,858,000	23,125,000

Germany does not figure in this table, as it only exports from one part what it imports in the other.

GARDEN.

A CORRESPONDENT of the *Garden* says that some have an idea that a tree cannot be moved successfully without a large ball of earth being attached to the roots, but where there is not sufficient machinery for the purpose failure is often the result. The system of moving he recommends is to begin at some distance from the base of the tree, rather further, in fact, than is generally practised, and to comb the soil away from the roots, injuring them as little as possible. If a tree be gone properly round in this way, and the roots saved, success is perhaps more certain than when trees are transplanted with large balls. This can be taken as a contribution to the discussion of the important question of moving large trees. The success of the plan can only be demonstrated in practise.

THE insects that attack the orange tree are cocci, probably coccus hesperidum, a species pretty common to other plants as well as the orange. They can be destroyed by using either Fowler's insecticide, or Gishur's compound, or the following—soft soap, 2 lbs.; flour of sulphur 1½ lb.; tobacco, 1 lb.; and a wine-glassful of kerosene. Mix, and apply with a strong painter's brush. The destruction of these insects and the mussel scale so prevalent on orange trees should be commenced as soon as they appear as they do great injury to the trees, both by the extraction of juices and clogging up the breathing pores of the bark. The pests may often be avoided by destroying the gravid female coccus, who at periods may be seen climbing the trees and depositing her young. Try kerosene and water in proportion of three wine-glassfuls to seven gallons of water, and apply with a strong syringe. It is highly spoken of as an insect destroyer. Keep the mixture well stirred with the syringe while using.

WORMS IN FLOWER POTS.—A correspondent of the Irish *Gardener's Record* writes as follows under this heading:—"Have any of your readers tried mustard water for the purpose of destroying worms in flower pots? I have, and found it to answer admirably. A tea spoonful to a gallon of water is sufficient. I have never known it to cause the slightest injury to the roots of the most delicate plants. I advise any one troubled with this pest to give it a trial." We will give it a trial. There is one great advantage about the employment of mustard for this purpose, that as it is invariably kept in the house it is always handy for use; whereas lime, with which to manufacture lime-water is not always so available. Worms in pots are a great nuisance, but a humanitarian gardener has remarked, "earth-worms should never be ruthlessly destroyed; they are appointed by nature to ventilate the subsoil by boring in it channels for the ... [illegible] of air."—*Land and Water.*

BUFFALO HORN AS MANURE.—A few days ago we saw some chrysanthemums in pots that were very remarkable for the vigour and healthy appearance of their foliage, and on making enquiry we found that when the plants were shifted into their blooming-pots a good dressing of buffalo horn manure was given in the soil. We have heard of this as a most excellent manure for vines, strawberries, &c., and the appearance of these healthy chrysanthemums proves that it is well suited to them also. The shavings which constitute the manure are small, and a great deal of it is little better than powder; it readily mixes with the soil, and it is undoubtedly rich in nutritive properties. Unlike some of the chemical manures, it is free from injurious ingredients, and can be safely used by all classes of gardeners. We have ourselves made a few experiments with the buffalo horn manure, and are well satisfied with the result.—*Ibid.*

HINTS TO GARDENERS FOR JANUARY.

WATER all hardwooded plants, examine each plant, and those that need water should have enough to moisten each particle of soil. Should there be reason to think that the roots are "balled" with hard clay, pull up the plants and soak the roots in tepid water or uncover them and sluice them well with it. With regard to glass-house specimens, regulate the growth of Dipladenias, Stephanotis, Clerodendrons, other plants of a scandent habit, that, are grown into specimens. Those only starting into growth should be syringed frequently, and not have too much water at the roots. Ixoras should have bottom heat, either by being plunged in a hot-bed or stood on the surface. Rondeletia Speciosa is a grand subject when it has justice done to it. It must not be allowed to have too much water, but if it is allowed to become very dry, it will shed its leaves. Keep the Selaginellas in a shaddy part of the house to enable them to retain their fresh delicate green colour. Gloriosas and other tuberous-rooted plants will require more water as the young growths begin to show above the surface. Let nothing suffer for the want of water.

FORCING HOUSES.

Fig House.—Keep the syringe freely at work amongst the foliage to prevent its being infested with Red Spider, for it is impossible to have a good crop of fruit if the foliage is unhealthy. Free ventilation without the foliage being exposed to the influence of keen blasts of wind is an important point in fig growing. All suckers must be removed and very strong growths stopped at 4 or 5 leaves above the old wood. See that the borders are not becoming dry. Trees in pots must be encouraged with weak lime manure. A layer of half-rotted horse droppings on the surface of the soil will assist these.

Pinery.—The whole of the stock excepting recently-potted suckers and crowns should have a slight syringing on warm afternoons. Plants that are required to stand for fruitings must not have too high

a temperature, 75° or 80° for bottom heat must not be exceeded and 10° lower for top heat. Ventilate freely to keep the young growth stocky. As we write these notes there are some two score young plants within a short distance of us, along the shady side of a water course, for watering a compound, all doing well. A "Sucker" planted alongside stable manure under a shady wall, has turned out a strong and hardy plant far in advance of the others we mention. Altogether we incline to "shade" for Pine-apples, although the Superintendent of the Maida Vale Pinery in London having tried all kinds of experiments cannot say positively what circumstances are most favourable to the development of pines. As a matter of fact, in the West Indies and South America, they grow anywhere and any how.

Strawberry House.—Any glass shaded stand will do; expose the plants to light and air, or they will have flavourless fruit. Discontinue liquid manure, upon symptoms of the leaves withering.

Vinery.—Stop back all laterals to one joint beyond the main spur, and the later spurs to one or two joints beyond the bunch. Thin out the bunches before the berries become too large, or they become crowded and render the task difficult without injuring those that are to remain. Look after the inside borders, and maintain an abundance of atmospheric humidity. Mr. D. S. White, Kilpauk, Madras, has freely experimented on vines, and now possesses some magnificent ones, extending over 60 yards in length, on two sides of his bungalow, and supported on posts 15 feet high; the vines are then trained across a trellis work overhead, 15 feet wide, the walk underneath being deliciously cool and shady.

Flower Gardens and Pleasure Grounds.

Purchase rock plants, as their character may be seen in the foliage, and many are in flower now. Sandy loam is the best for filling the fissures of rock work for the general collections. Roses from pots can be planted out now, for another six weeks with success. If the plants come to hand in a free-growing state, keep them in a cool airy frame for a fortnight or three weeks, to well harden before planting. The wild rose from the ghâts can be grown in beautiful profusion on ornamental rockeries. Stir the soil of tulip beds and tread Ranunculus beds carefully between the rows. In dry weather water them well. A mulch of cocoa-fibre refuse or well decayed manure will render watering unnecessary. Tritomas can be propagated now by taking off the strong side-suckers and planting them in rich sandy soil. The seed of these plants ought to be sown soon in a cold frame or a very slight hot-bed. Sow four or five seeds in each pot, turn the seedlings out into the border with the ball entire, and take up and divide in the spring.

Kitchen Garden.

Cabbages are 12 annas and 8 annas each in Madras, and as to lettuces, they are as rare as the Dodo in its ancient haunts. The square miles of compounds full of weeds and rubbish are a standing monument of the passive obstinacy of butlers to prevent their master's cultivating even a mouthful of green food "out of the market" to stimulate their torpid livers. However, perhaps some of the "Benighted" may read, mark, and learn that, in December and January asparagus seed may be sown with safety. Every man requires 10 per cent. of potash in his blood and he may just as well get it by cultivating and eating asparagus as by paying a doctor for Eno's fruit salt. The young asparagus plants must be thinned out, as soon as they are large enough to handle. Where any of the second sowing of peas has missed through being destroyed by birds or mice, stir up the soil and plant asparagus. Sow vegetable marrows, cucumbers and melons in manure-beds. Always remembering that, such plants grown in a cool temperature are stronger than those in a hot; to plant them all in 9 inch pots saves time. Sow for succession peas, beans, lettuce cabbage, cauliflowers, endive and small salading. And if anybody, native or European, tells you "they won't grow," say, you mean to persevere them until they do grow.

POTTING AND TRANSPLANTING.

NEVER put a small seedling in a large pot; for it only looks lonely and out of place, but will not thrive as if placed in a thumb-pot. Roots are either annual, biennial, or perennial; and under all circumstances the fibrous parts (radiculæ) are strictly annual, and as the winter approaches decay or remain in a state of rest, as we term it, until spring returns, and then renew their vigour, which we perceive by the formation of new leaves. Plants or trees may always be more successfully transplanted when these fibres are in a state of decay; for, being of so tender a texture, there is always the liability of breaking and injury, from the hand of the amateur, and, of course, the removal will necessarily cause a cessation of labour on the part of the plant. They are dainty objects, and will rest after moving from their old home to a new one; and from them we may all learn many an invaluable lesson. Many of you last spring, after the toil and weariness of moving and house-cleaning, took no thought of the body needing rest, and now in the sultry days of summer feel the need of it, and acknowledge, when too late, that had you been more careful then you would not be obliged to suffer so dearly for your imprudence now. Always, if possible, transplant when these fibrous roots are in a state of decay, for the roots almost exclusively imbibe nourishment from these fibres, and in proportion as they are injured by the removal, just so much is the plant deprived of the means of support, for that sap which is now employed in the formation of new fibres would have served to increase the size of other portions of the plant. If your plant produces seed in large quantities, the fibrous roots exist only in a very limited number, and, *vice versa*, the production of seed, particularly in tuberous-rooted plants reduces the amount of root developed.

In nurseries I believe it is usually customary to prune the roots of trees which are being transplanted. If at any time a root becomes bruised, it should immediately be removed, lest it decay and thus affect the neighbouring parts, and may, if not removed, cause the loss of tree or plant. This operation should be performed in the fall, for then the roots, like the other portions of the plant, are comparatively empty of fluid; but if you wait till spring you rob it of much of the vitality which it has been hoarding up for its spring compaign, and thus retard the prospect of future success to a late day. If you wish some of your shy-blooming tuberous-rooted plants to bear seed, keep the tubers pulled off, for then the sap is thrown upward; and if, on the other hand, the tubers are desired, pinch off the blossoms. Some of us have been taught that it was much more difficult to obtain seed from the early potato than from the later varieties. By simply removing the tubers they will blossom, and give us as great an amount of seed as the late ones.

In watering plants or trees we are accustomed to pour it on the stem or body, and not on the ground surrounding it. Years ago a successful experimentalist discovered that by placing a radish in water it would imbibe freely if only the extremities were placed therein; but if plunged in entirely, imbibed but little and soon wilted. This fact explains why the skilled gardener waters his trees and shrubs at a distance from the trunk or stem. While recently watching the rain drop peacefully from the clouds, I thought perhaps this is why the leaves act as a roof for the large roots, collect the drops which run from one to the other, and at last fall from the outer edge, which serves as an eave, and brings the greater portion of moisture just where it is most needed to cause these fibrous roots to push forth and seek larger quarters. The food imbibed by the roots is slowly and with much labour carried to the vessels off the stem and branches, and there deposited. The roots usually are incapable of increasing the family of plants to which they belong. Still there are some exceptions, and certain species have the power of forming what are called adventitious buds, and are thus useful for the purpose of propagation. I believe there is no known rule to determine what species may be thus increased; and, therefore, experiment must be brought into practice. If at any time it becomes necessary to prune a root, leave it with a smooth, clean surface. If small roots are bruised they die back a little and then send forth new roots; but if the large ones, they lose their vitality, and, as their ragged tissues remain open to the frequent introduction of water, decay is the result, and the disease spreads to the healthy portions of the plant and death is usually the result. In many cases it is wise to remove a portion of the large root, and thus compel the plant to throw out young, active fibres in place of those which have for a season seemed inactive. Extensive growers of the gooseberry annually dig along their borders with a sharp spade and cut off the roots, thus causing the increase of branch and fruit. By careful observation we may always tell when the roots of our plants need more soil or new quarters. It is not necessary to remove the plant as soon as the roots begin to curl round the edge of the pot. Let them grow freely; but do not let them become dry and woody. They should be white and succulent. When changing a plant from a small pot to a large one, be particular not to destroy these tender fibres, and, after placing the ball of earth in the centre, pack the soil moderately firm in the space. After repotting stand the plants where they may have a free circulation of air around the pots, and the roots will be much stronger and more healthy, while that have stood crowded together have made but little progress in root formation or upward growth. Many times florists, instead of removing a plant to a larger pot, simply wash the soil from the roots and return it to the same pot, but in a new soil. This is why they use such comparatively small pots for large plants. By washing the soil from the roots the fibres are uninjured, and the plant can go on in its labour or forming leaves and blossoms; while if we break the soil from the roots we break the fibres also.
—*Fern Leaf.*

AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

The usual Monthly General Meeting was held on Thursday, the 28th November 1878.

THE HON'BLE L. S. JACKSON, C.I.E., *President, in the Chair.*

THE proceedings of the last meeting were read and confirmed.

The following gentlemen were elected members :—

The Superintendent, Botanical Gardens, Saharunpore, Mr. Charles Roberts, Manager of the Nohabarree Tea Estate, Assam, and Manager of the Punkabarree Tea Company, Punkabarree.

The names of the following gentlemen were submitted as desirous of joining the Society :—

Walter Knaggs, Esq., Trafalgar Estate, Singapore,— proposed by the Secretary, seconded by Mr. W. H. Cogswell.

Edward Scarth, Esq., Ningri Ting Tea Factory, Assam,—proposed by Captain W. J. Williamson, seconded by Dr. E. Gray.

Baboo Grija Prosunno Mokerjee, Zemindar, Goburdanga,—proposed by the Secretary, seconded by Mr. J. E. MacLachlan.

The Hon'ble Justice Wilson,—proposed by the President, seconded by Mr. W. S. Creswell.

CONTRIBUTIONS.

1. Transactions of the Asiatic Society of Japan, Vol. VI., Part 2. From the Society.

2. Journal of the Asiatic Society of Bengal, Part I, No. 2, and Part II, Nos. 2 and 3, 1878. From the Society.

3. A number (88) of rare mango grafts, and 12 lychee grafts prepared in his garden at Utterparah. Presented by Baboo Rajkissen Mookerjee. A special vote of thanks was accorded to the Baboo, for this acceptable donation.

4. A case of plants from the Botanic Garden at Signapore. Presented by the Superintendent.

5. A small quantity of seeds of tuberous *Begonias* and of *Momordica sanguinea.* From Samuel Jennings, Esq. (Transferred for sowing in the Garden.)

6. A packet of Geranium seed from Naini Tal plants. From T. M. Francis, Esq.—Transferred to Garden.

7. Four varieties of Patna millets. From John Scott, Esq.

8. Seed of the "Forbidden fruit." (*Citrus*—— ?) From the West Indies. From Col. W. M. Lees.

9. A few more seeds of the "Aki" (*Blighia sapida*) and of Ladak tobacco. From the Department of Agriculture, N.-W. P.

10. Four healthy seedlings of the tea plant from Assam. Presented by W. E. Smith, Esq.

GARDEN.

THE Gardener's monthly report was read as follows :—

" The weather having become more open during the month, the grass-cutting work of the coolies was somewhat lighter, which gave an opportunity for utilising their services in a more general way, making new roads, repairing existing ones, and tidying up for the cold season. As authorised, twelve extra hands have been secured for a time to prepa[re] flower-beds, repair roads, &c., as the original staff are all engaged in the afternoon watering which, as our water-supply stands at present, will always prove an heavy item nine months out of the twelve. Potting off young stock, fruit grafts, &c., taking off rose layers sowing seeds, and watering have occupied the *mallees'* attention, to say nothing of the D. O.'s, which are as brisk as ever. The Liberian coffee seedlings are, I find, of extremely slow growth ; a couple of seeds of the second sowing (sown 1st October 1878) have germinated. In this same pan I tried a few green berries, but otherwise firm and full sized, and apparently only requiring a few days more to colour, but they failed to germinate. This would seem to indicate that the berries must be left on the plants till they are coloured more or less. I have hopes that I shall be able to succeed better with the cuttings as soon as I get some bottom-heat in the propagating house. A case of plants has been received from the Singapore Botanic Garden, the plants being in fair condition. Consignments of various other seeds have been received and duly sown. A paper, shewing the percentage of germination of vegetable seeds in the trial sowings of 1878, is herewith enclosed ; they were all sown under exactly the same conditions. The seeds from Messrs. Sutton and Sons, of Reading, have certainly taken the lead in both germinating powers and robustness of the seedlings. A report of the germination of the imported flower seeds will be sent in next month."

The tabular statement of trial sowings shews that the English seeds have germinated best, and the American second, whilst [the] French and German have germinated but indifferently. It was agreed to reconsider this at the next monthly meeting, when the trial sowings of flower seeds will be submitted.

REPORT ON THE COMPARATIVE WORKING OF CERTAIN PLOUGHS.

THE following report from Dr. S. Lynch on the above subject was submitted :—

"I return herewith the plough you were good enough to lend me for the purpose of testing the draught when used on the light soil of the field attached to the Alipore Jail. The plough is one of Ransome's very light ones, its weight being only 84lb. The depth of the furrow was between five and six inches, and the width about seven. We found the draught when the plough was drawn by a pair of bullocks at their ordinary pace, was between 2½ and 3 hundred weight on land from which a crop of millet had just been cut. The bullocks used were average country animals, well fed, and accustomed to ploughing. The plough, with the same bullocks, was also tried on grass land which had never before been turned up—the site of an old village. Here the draught was as much as 4 cwt. to 4½ cwt. This was as much as the bullocks could manage, walking very slowly, and they could not have done a day's work at it. The land was wet and heavy.

" The work of a native plough was compared on the same grass land with that of the English plough ; the draught was found to be 1½ cwt.: such a trial is of little use, as the native plough is not intended to accomplish its end in the same manner as the English plough. It scratches the ground and has to go over the same surface repeatedly to get to the depth which the English plough reaches at once.

" One result of testing the draught of the native plough was that we found that bullocks, such as are used here in native carts, are equal to a draught of 1½ cwt. Anything more brought them to a stand-still. The work done therefore by the native plough is equal to the capacity of the country bullock when half-starved in the hands of the poor native.

" We also compared Ransome's plough with an American wooden beam plough with wooden handles, made at the jail from a pattern you were good enough to lend us. This plough weighs about 56 pounds (the weight varying according to the kind of wood used). The ploughshare is a bar of wrought iron, made to shift forwards as the point wears out. This plough turning the same furrow as to depth and width as Ransome's, but a broken one, whilst with Ransome's the work was beautifully even, the slice being turned completely over showed the same draught as Ransome's.

" Comparing the two ploughs as to cost, the American plough can be made here at from Rs. 12 to Rs. 15, whilst light English ploughs for a single horse or pony cost at home from £2-10 to £3, or in this country, from Rs. 45 to Rs. 50. The difference, then, is altogether in favour of the locally-made wooden plough, which turns out just as efficient work, though not so good to look at as the English one, which is far lighter,—56 lb. against 84 lb.,—and can be made at one-third of the cost of the English plough."

RESULT OF SOWINGS OF "REANA LUXURIANS" AND "LUCERNE" IN THE AGRA DISTRICT.

The subject next introduced was a communication from the Manager of the Agra Ice Company regarding the cultivation of Lucerne grass and Reana luxurians :—

" Some of the seeds of Reana luxurians, with which you kindly furnished us, sown in April last 6 feet apart, produced 30 to 40 seers weight of fodder at first cutting in September. Seeds sown in October of last year, surviving the winter and one sharp white frost on 6th January this year, yielded a first cutting in April and a second in October ; but on the whole we think the soil more profitably employed with Lucerne, which, *except in the rains*, when indigenous weeds and excess of moisture seem to choke it between them, yields a fair cut, even on our poor soil, monthly, and doubtless with manuring (which we purpose) the plants, which are now springing into a vigorous resuscitation quite refreshing to the eye in this dull brown barren looking locality, will exceed their former outturn. A plot sown in September 1876, nearly killed by the long drought of 1877, yielded early in this year repeated cuttings of 24 to 30 inches in length, and good substantial thickness of stalk in 25 to 30 days ; in one case we noted 30 inches in 21 days. We have abundance of water and irrigate so as to keep the surface from absolute dryness ; beyond this, this plot had no manure until later on. The soil is a mixture of sand, yellow loam, and small *débris* of building—poorest stuff.

" We note these facts as they may interest you, or serve to inform some one who wants to know about Lucerne, which strangely enough seems little known in this district."

PROGRESS OF COFFEE AND TEA CULTIVATION IN THE ANDAMANS.

Read the following extract of a letter dated 10th November, from Mr. O. H. Brookes, on the above subject :—

" I went to inspect the tea plantation at the new clearing on Saturday last. The plantation is situated on rising ground about 150 feet above the level of the sea ; there are about four acres of land under tea cultivation, and there are approximately about 10,000 plants. The first beds planted look remarkable healthy ; they were planted out about

March, and are now on an average about 18 inches high, and have thrown out four and five stems each. These plants were raised from China seed. There are also Assam plants of more recent planting and consequently lesser growth; but these too are looking strong and healthy; the plants are planted about five feet apart: field rats are destructive to the small plants, but the introduction of cats will prevent this to a great extent. The coffee plantation at Mount Harriet is in a flourishing condition. I have seen some of the plants almost breaking with the weight of the berries; there are about 120,000 plants, and of these there are about 30,000 now in bearing, and we anticipate a crop of from 8,000 to 10,000 lb. of coffee this season, so we shall hereafter be well off in coffee and tea. Sugar could be manufactured in large quantities, as the cane grown here is excellent. In 1881, when all the coffee plants will be in bearing, we ought to get a crop of 50,000lb. of coffee."

REMARKS ON THE PAST SEASON IN THE BENARES DISTRICT.

The following communication from Mr. C. Nickells, of Pussena Factory Jounpore, was next submitted :—

"At the monthly general meeting of the Society held on the 24th October, under the head "Horticultural Notes," a letter was read from your Benares correspondent. He says,—"The damp is excessive, and again such rains have not visited Benares for ten years." I am an indigo planter, and my experience tells me, and I am sure all planters will agree with me, that the past rainy season has been an *excessively light one* with two exceptions,—*viz.*, 1873 and 1877. The showers were few and far between, and the heaviest fall did not exceed 2½ inches; the damp was certainly not excessive, and the little rain that did fall came at the right moment, which was the principal cause why the *khurreef* crop was so fine.

"I cannot agree with your correspondent about the past being the heaviest rainy season within the last ten years. The years 1874 and 1875 were indeed heavy rainy seasons; in those years the rains began early and left off late. It rained sometimes for a fortnight at a time, and five to ten inch showers were of common occurrence. In the flat lands water flowed out of the wells, and of course the *khurreef* crops were an entire failure: even the succeeding *rubbee* did not do well owing to the lands not being ploughed sufficiently.

"I don't think the crops (*rubbee*) will be fine this year unless rain falls soon. There is hardly any moisture in the ground, at least not sufficient to mature the crops."

Letters were read—

From Col. M. H. Lowther: a few hints in connection with a *Gardner's Note Book*.—Transferred for journal.

From T. M. Francis, Esq.: the substance of a paper in the *American Agriculturist*, regarding a novel mode of putting down cuttings of hard wooded plants—Transferred for Journal.

From Samuel Jennings, Esq., a few notes on tuberous *Begonias*.—Transferred for Journal.

From the Deputy Conservator of Forests, Tounghoo Division, applying for a quantity of tea seed for the Thandoungyer plantation.—To be complied with.

From the Secretary, Royal Horticultural Society, London, returning thanks for certain seeds.

Before the meeting separated Mr. James Caldwell drew the attention of members to a collection of forty-four water colour paintings, full size, of as many varieties of sugarcane collected by him in New Caledonia in 1869 and 1870, for the colony of Mauritius. The whole of these, with many other kinds from other localities, were introduced in Wardian cases, to renew the original cane plants previously cultivated, which had so deteriorated, from long and exhaustive cultivation, as to bring the sugar industry and the colony to the verge of ruin. The result was completely successful, and the orginal outlay advanced by the Government was not only fully repaid, but left a considerable surplus. The paintings now exhibited were made in New Caledonia from the plants, as actually collected, by Madame de C. Moon, a distinguished amateur flower painter (who has largely illustrated the botany of Mauritius), and from their truthfulness and finished execution, they form a singularly interesting collection, as remarkable for their unexpected varieties of colouring and form as for their novelty.

The best thanks of the meeting were accorded to Mr. Caldwell for the exhibition of these drawings, which were much admired, and for his remarks thereon.

Mr. Caldwell kindly consented to allow the portfolio to remain for some weeks in the Society's rooms for the inspection of those who take an interest in sugarcane cultivation.

AGRICULTURAL SHOW IN KHANDEISH.

TO BE HELD AT MAHEJI FAIR, KHANDEISH.

Opening day, Monday the 3rd February, 1878.

ALL articles including Live Stock must be delivered not later than Saturday the 1st February at Maheji, after which date they will not be received. This does not apply to vegetables and such like perishable articles which will be received up to the morning of the opening of the Exhibition or up to date of examination.

All articles intended for exhibition, should be consigned to the care of the mamledar at Maheji.

The Exhibition will be open to the public on Monday the 3rd February 1879, but the first few days will be occupied by the Committee in judging &c. Prizes will be awarded on Saturday the 8th February.

No prize will be given in any class unless the stock exhibited comes up to a fair standard of excellence.

Committee reports to be sent into the Collector by Friday morning (7th February) by the latest.

Mamledar to be informed by the Judges of their awards not later than Friday morning (7th February) so that arrangments made be for getting the money ready &c.

A.—HORSES.—30 *Prizes. Total Rs.* 1,695, *for bona fide native breeders.*

		Rs.
1.	For brood mares over 14 hands, the produce of any Government stallion and in foal to, or with foal at foot, by a Government stallion. If "in foal" to be not less than 4 years or "with foal" not less than five years old. There prizes of Rs. 150, 100 and 50	300
2.	For brood mares of any breed not less than 14 hands and one inch, with foal by a Government stallion, or covered by a Government stallion. Four prizes of Rs. 100, 60, 40 and 20	220
3.	Colts one year old and under two, by Government Stallions. Three prizes of Rs. 60, 40 and 20...	120
4.	Geldings two years old and under three (any country breed) Three prizes of Rs. 75, 50 and 25...	150
5.	Ditto three years' old and under four (any country breed). Three prizes of Rs. 125, 75 and 40	240
6.	Fillies one year old and under two, by Government stallions. Three prizes of Rs. 60, 40, 20	120
7.	Ditto two years old and under three, by Government stallions. Three prizes of Rs. 75, 50 and 25	150
8.	Ditto three years old and under four, by Government stallions and likely to become a good brood mare. Three prizes of Rs. 125, 75 and 40	240
9.	Tanga Ponies, geldings, 13 hands and under, not being the property of a stipendiary Government servant. Two prizes of Rs. 40 and 25 ponies to be sold if claimed up to 80 rupees the pair	65
10.	Country bred ponies, geldings 13-2, and under and not more than 8 years old. Three prizes of Rs. 40, 30 and 20 ...	90

(No prizes to be given to prize-takers of previous years for the same animal and under the same head, neither can an animal get a prize under more than one head).

A hand is equal to 4 inches.

Entire colts or ponits allowed to compete as geldings, if the owners agree to geld them at Maheji.

B.—CATTLE—26 *Prizes. Total Rs.* 605.

11.	Best bull of any breed and independent of age, one prize	50
12.	Country-bred bulls over *two* and under *four* years of age, 3 prizes of Rs. 40, 20 and 10	70
13.	Milch cows, four prizes Rs. 30. 20, 15 and 10	75
14.	Field bullocks, nine prizes of Rs. 50, 40, 35, 30, 25, 20, 15 10 and 10	235
15.	Bull buffaloes, two prizes of Rs. 20 and 15	35
16.	Milch buffaloes, three prizes of Rs. 35, 20 and 15 ...	70
17.	Bull calves by Government bulls, or bulls bought from the *herd*, 2 prizes Rs. 20, 15	35
18.	Cow calves by Government bulls, or bulls bought from the herd, two prizes of Rs. 20 and 15	35

C. GRAIN AND SEEDS.—39 *Prizes. Total Rs.* 495.

(Each competitor to exhibit *fifteen* seers, certified to be the produce of a Survey, number of not less than 2 acres in his holding.)

19.	Wheat. 3 prizes of Rs. 20, 15 and 10	45
20.	Gram, 3 prizes of Rs. 20, 15 and 10	45
21.	Rice indigenous, 3 prizes of Rs 20, 15 and 10	45
22.	Rice Carolina, 1 prize Rs. 20	20
23.	Bajri, 3 prizes of Rs. 15, 10 and 5	30
24.	Jowari, 3 prizes of Rs. 15, 10 and 5	30
25.	Linseed, 3 prizes of Rs. 20, 15 and 10	45
26.	Tilly, 3 prizes of Rs. 20, 15 and 10	45
27.	Any other oil seeds of Khandeish, 3 prizes 20, 15 and 10 ...	45

(For the following, each competitor to exhibit *ten* seers certified to be the produce of a Survey number of not less than two acres in his holding.)

28.	Tur, 3 prizes of Rs. 15, 10 and 5	30
29.	Kulthi, 3 prizes of Rs. 15, 10 and 5	30
30.	Urid, 3 prizes of Rs. 15, 10 and 5	30
31.	Mug, 3 prizes of Rs. 15, 10 and 5	30
32.	Peas, 2 prizes of Rs. 15 and 10	25

D. COTTON—17 *Prizes. Total Rs.* 320 *and a Gold Medal.*

(Each competitor to exhibit 25 seers grown in Khandeish, certified produce of one field.)

33.	Cotton, Hinganghat variety uncleaned, 4 prizes, 2 of Rs. 25, and 2 of Rs. 20 each	90
34.	Ditto Dharwar ditto 4 prizes, 2 of Rs. 25 and 2 of Rs. 20 each	90
35.	Ditto Hinganghat, cleaned, 4 prizes, 2 of Rs. 20 and 2 of Rs. 15 each	70
36.	Ditto Dharwar ditto 4 prizes, 2 of Rs 20 and 2 of Rs. 15 each	70
37.	For the best of all samples of cotton exhibited, a gold medal or cash Rs. 100	100

E. Fibres—18 *Prizes. Total Rs.* 210.

(Each competitor to exhibit ten seers.)

38.	Hemp (saun), 3 prizes of Rs. 20, 10 and 5	35
39.	Hemp (Ambari), 3 prizes of Rs. 20, 10 and 5 ...	35
40.	Aloe fibre, 3 prizes of Rs. 20, 10 and 5	35
41.	Cotton stock, fibre (Palkati) 3 prizes of Rs. 20, 10 and 5 ...	35
42.	Jute fibre, 3 prizes of Rs. 20, 10 and 5	35
43.	Other ditto ditto	35

F. Tobacco—12 *Prizes, Total Rs.* 220.

(Each competitor to exhibit 10 seers certified produce of one field).

44.	Tobacco indigenous grown in Khandeish 6 prizes, 2 of Rs. 25, 2 of Rs. 15 and 2 of Rs. 10	100
45.	Tobacco exotic grown in Khandeish, 6 prizes, 2 of Rs. 30, 2 of 20, and 2 of 10	120

G. Dyes,—3 *Prizes, Total Rs.* 45.

(Each competitor to exhibit *ten* seers which must be certified to be a fair sample of two maunds.)

46.	Indigo prepared in Khandeish, 1 prize of Rs. 20 ...	20
47.	Al. 1 prize of Rs. 15	15
48.	Kusumb, 1 prize of Rs. 10	10

H. Sugar Cane and Sugar—19 *Prizes, Total Rs.* 385.

The former to be exhibited in samples of *fifty* canes, as certified samples of the produce of not less than an acre.

The latter in samples of one *bhili*, approximating a *maund* in weight.

49.	Mauritius or Nagar Dewla canes, six prizes of Rs. 35, 30, 25, 20, 15 and 10	135
50.	Black canes, four prizes of Rs. 25, 20, 15 and 10 ...	70
51.	Khudia canes, three prizes of Rs. 20, 15 and 10 ...	45
52.	Goor prepared in Khandeish, 6 prizes of Rs. 35, 30, 25, 20, 15 and 10	135

I.—Roots and Vegetables—14 *Prizes, Total Rs.* 63.

(To be exhibited in samples of not less than five seers.)

53.	Potatoes common, grown in Khandeish one prize ...	20
54.	Ditto sweet grown in Khandeish (Ratalas) one prize ...	5
55.	Onions Ditto ditto ditto ditto ...	5
56.	Wangi Ditto ditto ditto ditto ...	3
57.	Chillies-grown in Khandeish, one prize ditto	3
58.	Carrots Ditto Ditto ditto ditto	3
59.	Garlic (lasen) Ditto ditto ditto ..	3
60.	Beet root Ditto ditto ditto ...	3
61.	Turnips Ditto ditto ditto ...	3
62.	Lettuce Ditto ditto ditto ...	3
63.	Nohlkohl Ditto ditto ditto ...	3
64.	Cauliflower Ditto ditto ditto ...	3
65.	Cabbage Ditto ditto ditto ...	3
66.	Tomatoes Ditto ditto ditto ...	3

J. Textile Fabrics—14 *Prizes. Total Rs.* 135.

Not less than 3 pieces of each description of fabric to be exhibited, by each individual competitor, for a prize under any class, and to be certified by the *mamledar* of the *taluka*, that they are *bona fide* Khandeish made by the exhibitor, or his family.

Fabrics to be sold if claimed for the price fixed in the class under which they compete.

67.	Sarees of the value of Rs. 12, one prize	15
68.	Ditto ditto 6 ditto	7
69.	Ditto ditto 3 ditto	6
70.	Dhoties of the value of Rs. 12, one prize	15
71.	Ditto ditto 8 ditto	11
72.	Ditto ditto 4 ditto	7
73.	Turbans of the value of Rs. 18, one prize	16
74.	Ditto ditto 7 ditto	10
75.	Ditto ditto 4 ditto	7
76.	Carpets, two prizes of Rs. 20 and 10	30
77.	Simple Dungree, one prize	5
78.	Double ditto one prize	5
79.	Country Blankets, one prize	5

K. Carts &c.—6 *Prizes. Total Rs.* 150.

80.	Baggage carts exhibited for sale at a price not exceeding Rs. 40, to be sold if claimed, two prizes of Rs. 30 and 20	50
81.	Riding carts exhibited for sale at a price not exceeding Rs. 40, to be sold if claimed, two prizes of Rs. 30 and 20	50
82.	For the best tanga or cart on springs to be for sale, two prizes of Rs. 30 and 20	50

L. Miscellaneous—2 *Prizes. Total Rs.* 40.

83.	For the best lac not less than five pounds in quantity and gathered in Khandeish, one prize	20
84.	For the best set of native field implements consisting of 1st Nagar (plough) 2nd Wakhar (hoe) 3rd Kolpe (weeding hoe) 4th pamer (seed depositer) one prize .	20
	Total Prizes Rupees ...	1,460

FORESTRY.

In view of the circumstances brought to light in the report of the Neilgherry Forest Reserve Commission and otherwise forced on the notice of Government, the Governor of Madras in Council resolves to direct that no application for Forest or Shola land be entertained on the Neilgherries until the whole district has been reported on, and the general question of land reservation, whether forest or grass land, been considered, and future policy decided. Any such applications addressed to the Commissioner will be registered for future disposal.

The endeavour made to cultivate trees other than those indigenous to Mysore, in some of the Government fuel plantations, does not appear to have met with encouraging results. Experiments were tried with the Carob, Mahogany, Red Saunders, Sal, Wattle (Acacia Dealbata) Gum Trees, (E. Robusta and E. Globulus). Australian, Blackwood and Silk Oak (G. Robusta). The Carob has grown well and so have the Mahogany, of which seven only have been planted; the Eucaplipti have suffered a good deal, specially the small plants. The Grevilla Robusta (Silk Oak) does not appear to have been tried on a large scale; a fine cluster of these trees is to be seen near the slaughter-house in the Cantonment, but the tree is not fit for fuel or timber. To make plantations a source of future revenue, steps ought to be taken to sow trees broadcast, by means of ploughing—pitting out is an expensive process, and transplanted trees do not grow so robust or quick as seedlings left to themselves. A good specimen of this kind of forest-making may be seen near Jacoor, where a tract of land was so dealt with by Mr. Ricketts some years back and is now a dense growth of fuel.—*Bangalore Spectator.*

Some of the difficulties which will attend the management of arboriculture by the Department of Agriculture, have already been noticed in these columns. It is a hazardous experiment for one man to control and direct the scattered operations of a province comprising nearly fifty districts and nearly five hundred tehsils. It is doubtful whether any more satisfactory results will be obtained than under the old system, by which Collectors with a fancy for tree-planting got a good deal done through the tehsildars. After all the new system throws on Collectors the task of carrying out operations decreed by the Department, and superadds the risk of possible friction with public works officials. A grant is made to the former for planting and to the latter for maintaining avenues. The question naturally arises when is the responsibility of maintenance to commence? The district officer may gaily spend his pittance of five hundred rupees in planting a first-rate avenue, which he will hand over to the P. W. D. to maintain out of their still more insufficient allowance. Trees will die, who is to replace them? The Collector vows he handed over strong and healthy trees to the District Engineer; the latter recriminates perhaps that the trees were made over insufficiently protected, or, as is the fashion now-a days, surrounded by vast trenches that are no protection against the active goat, and may drain off the moisture from the roots of the sapling. No doubt all these points can be disposed of by a few simple rules, but the period of transition in management is not likely to have been favourable to arboriculture. *Apropos* of arboriculture, it should be recollected that it is not enough to stick a sapling, however strong, into a hard dry soil. The ground should be thoroughly broken up to a considerable, depth, and where the avenue passes through *usur*, the sterile soil should be replaced by good earth from a neighbouring field (very little is required). Heat above and drought below kill thousands of trees, especially deciduous trees (such as the shisham, &c.) Water should be given plentifully, and a good top dressing of old manure will stimulate the growth marvellously. Free planting is but a form of gardening, and we may look in vain for avenues if their nursing is left to the care of an ignorant road coolie. Planting must be limited by the funds available for thorough superintendence.—*Pioneer.*

SUBMERGED FOREST ON BOMBAY ISLAND.

Observations by G. E. Ormiston, *Resident Engineer, Bombay Port Trust, dated 29th May* 1878, *(communicated by Government).*

The strata exposed in the excavation for the Prince's Dock consist of the surface silt or black mud, which overlies to a depth of from 4 to 5 feet a dense blue clay of varying thickness (from 6 to 20 feet), but nearly level on top; underneath this is found loam, moorum,* and rock; the latter is very irregular on the surface, running at times into long narrow ridges and masses of boulders with

* A local term for decomposed rock.

soil between. The rock is soft, and consists mostly of indurated clay nodules imbedded in a hard matrix. Numbers of trees have been found (about 260 up to date). Many had been overturned before being covered with the blue clay, but the roots were only partially torn out of the loam or moorum in which they grew, others were standing upright with their roots deeply planted in their native soil. The standing trees only extend to the surface of the blue clay, none penetrated the muddy silt above ; and for a foot or so below the level of the blue clay, the timber was riddled by the *Teredo navalis*, or a similarly destructive worm. Most of the other trees also showed signs of this worm. One tree was found charred on one side for a short distance. The largest trunk found was 46 feet long and 4 feet 8 inches in girth ; some of the timber is quite sound ; it is of the colour of dark rose-wood, and with a straight grain. The level of the roots of these varied from low-water extreme spring tides to 12 feet under. This shows the land to have subsided at least 30 feet, as the trees must have grown above high-water mark.

NOTE.—This discovery of trees, in the spot on which they grew, below low-water mark in Bombay Island is chiefly remarkable, because it shews that, in recent or sub-recent times, depression must have taken place in the immediate neighbourhood of ground which appears to have been raised. The Prince's Dock is on the eastern or harbour side of Bombay Island, and the Esplanade surrounding the fort on the western side, not a mile away from the dock, is composed of the rock called littoral concrete by Dr. Buist, a mass of shells, corals and sand cemented together by carbonate of lime. It is scarcely possible that the materials of which this rock consists can have been accumulated at their present elevation above the sea; in all probability they formed, when first deposited, a sand bank or beach not raised above high-water mark, and as it is difficult to understand how elevation and depression can have occurred simultaneously on different sides of so small an area as Bombay Island, it is probable that the whole area has undergone elevation and depression alternately. If the elevation be the older movement, then the Esplanade must once have been several feet higher than it now is ; if the depression is older, the trees at Prince's Dock have been at a greater depth beneath the sea than they now are. The former is perhaps more probable.

The such alternate movements of elevation and depression have taken place in Bombay Island was shewn by Dr. Buist* many years ago, though to a smaller extent than now appears probable. At the same time, before the depth to which depression has extended in this case can be estimated, it is necessary to ascertain what kinds of trees are represented. If they be such as grow on land, the depression must have been greater than if they belong to such forms as *Avicennia* or *Bruguiera*, which grow some feet below high-water mark. The circumstance that the trees are bored by Teredo is in favour of their having grown in salt marsh, where these mollusca are peculiarly abundant.

W. T. BLANFORD.

MINERALOGY.

THE WYNAAD GOLD FIELDS—MR. SMYTH'S REPORT.

No. 1616 of 11th November 1878.

READ the following paper .—

From R. BROUGH SMYTH, ESQ., Mining Engineer to the Secretary to the Government, Revenue Department,—No. 169, dated Devalah, the 5th November 1878.

I have the honor to submit, for the consideration of His Grace the Governor in Council, the fourth report of my proceedings.

2. I have much satisfaction in stating that on the 17th October, gold was found in large quantities in a quartz vein about thirty chains south-easterly from the Alpha Mill, near an adit known as "Wright's Level."

3. The strike of the reef at the point where the "run" of gold occurs is nearly north and south, and the vein dips rather rapidly to the east. The average thickness of the vein is about four feet, and throughout a thickness of two feet or more ; the stone is veined and seamed with sesqui-oxyd of iron derived mainly from the decomposition of pyrites. Fine gold is disseminated throughout the blocks of stone which have been taken out, and it occurs also in well-defined layers associated with the ores of iron. When the blocks are broken, numerous jagged pieces of gold are seen, and thin leaf-like forms are found in some parts.

4. The yields of gold from the stone obtained at this spot have been as follows :—

		oz.	dwt.	gr.	
1.	No gold visible in the stone ...	0	11	6·0	per ton of 2,240lbs.
2.	No gold visible in the stone ...	2	16	1·6	ditto
3.	A little gold to be seen ...	56	13	19·5	ditto
4.	Gold visible in the stone ...	204	11	16·7	ditto

None of the richer specimens have been treated.

5. The "run" of gold appears to be transverse to the lines of the dip and strike of the reef, and I anticipate that at a greater depth, and at points north of the places where the rich stone is found, auriferous quartz will be discovered that will give good returns.

6. In an adit below Wright's Level, and nearly due east of the point where the richest specimens have been got, parcels of pyritous quartz has given an average yield of 3 dwt. and 23·04 grains per ton.

7. At the Skull Reef, about twenty-two chains north of Wright's Level there is a great thickness of quartz. It measures about fourteen feet from the hanging wall to a mass of 'floating rock' (country), but the total thickness has not yet been ascertained. Here there is at the face much stone that is practically unproductive. The reef has been carefully tested in five sections (vertical), and the yields, per ton 2,240lbs. were as follows :—

	oz.	dwt.	gr.
No. 1 Section.—Hanging wall one foot in thickness ...	0	0	16·19
No. 2 Section.—Hanging wall three feet in thickness ...	0	0	9·92
No. 3 Section.—Hanging wall four feet in thickness ...	0	1	2·20
No. 4 Section.—Hanging wall five feet in thickness ...	0	2	2·21
No. 5 Section.—Hanging wall six inches in thickness ...	0	0	4·25

8. It will be observed that the stone in the fourth section gave somewhat better yield than that from the other sections, and on tracing this line northwards along the strike, stone was obtained which yielded at the rate of 1 oz. 4 dwt. and 5 grains per ton.

9. Here, as in nearly all other cases, the gold is associated with sesqui-oxyd of iron, but clean gold in almost iron-free quartz is seen in some places.

10. The increased yield at the last-named spot appears to indicate the setting in of another band of auriferous quartz.

11. From a reef about forty-five chains south-easterly from the Devalah bazaar, I have obtained quartz which yielded in several sections as follows :—

	oz.	dwt.	gr.	
No. 1 Section ...	0	0	0 ...	Button not weighable.
No. 2 do. ...	0	9	1·91	per ton.
No. 3 do. ...	0	2	4·40	do.

The quartz from this reef contained a not very large proportion of pyrites.

12. Due west of this reef, and about twenty chains from it, there is an outcrop of auriferous quartz, and gold is also found in the soil near the reef

13. At the Cavern Reef, about twenty-six chains east of the Alpha bungalow, the native miners have made (for them) rather large adits, having evidently followed the direction of the pyritous seams, nests, and joints which are found there somewhat abundantly. These openings, as I am, informed, and from my own observations believe, have been worked, only to a very small extent, under the supervision of Europeans. The reef presents good prospects as indicated by the yields, which are as follow :—

		oz.	dwt.	grs.	
1.	Quartz	0	2	21·80	per ton.
2.	Pyritous quartz (the proportion of pyrites being large)	0	19	3·00	do.
3.	Pyritous quartz	0	10	2·59	do.
4.	Ditto	0	11	4·90	do.
5.	Ditto	0	8	5·60	do.
6.	Ditto	0	14	11·00	do.

This reef will be further tested as soon as other urgent work now in hand is disposed of.

14. A sample of pyrites which it is said was taken out of the Ettacu Reef (a portion of which has been laid bare by the Wynaad Prospecting Company, and which was formerly worked by the natives), has yielded at the rate of 2 oz. 1 dwt. and 7·78 grs. per ton. I have examined the abandoned workings at the Ettacul, and I have failed to find any mineral similar to that which I treated, but I have not yet had any quartz broken out. There is, however, no doubt, from the evidence I have obtained, that highly auriferous pyrites and pyritous quartz occur at this point.

15. The results here given are to my mind highly satisfactory, but any one result, whether large or small, if considered by itself and without reference to other facts connected with it, would be altogether misleading.

16. There are numerous reefs in the neighbourhood of Devalah, reported as auriferous, which I have not yet had the opportunity of examining, but quartz was taken from one reef some miles north of Devalah bazaar, and about four miles west from Nelakotta, when I was surveying there, and gold was found in it.

17. I have marked on the lithograph map of the three amshoms of South-East Wynaad (scale one inch to the mile) partly from my own observations and partly from information afforded by gentlemen resident in the districts, the position, approximately, of ninety outcrops of quartz veins, and west of Choladi, intersecting a line about fourteen miles in length, there are said to be eleven distinct reefs. It is not to be supposed, however, that during the short time I have been in the Wynaad I have been able to ascertain the position of all the reefs. There are many blank spaces on the map.

18. The position of the reefs is being marked down also on the Trigonometrical Survey map (on the scale of four miles to one inch), and from one reef three miles north-east from Vellirymulla, I am assured by a gentleman resident there, and who is acquainted with the reefs near Devalah specimens of auriferous quartz have been obtained as rich as any found in this

* Transactions of the Bombay Geographical Society, Vol. X., p. 177, 1857.

neighbourhood. My informant has been so good as to offer to point out the reef from which the gold was taken.

19. It may be regarded as certain that an area measuring twenty-five miles from east to west, and thirteen miles from north to south—three hundred and twenty-five square miles—is intersected by quartz veins in this district alone.

20. The great thickness of many of the veins and the formation of the country—which is such as to admit of the quartz being mined economically, no deep shafts or heavy expenses for the drainage of the mines being necessary,—have to be taken into consideration when the number of reefs is looked at and an estimate of the auriferous resources of the district is to be made.

21. Nor should the extensive, but shallow, workings of the native miners who sought for gold in times past be forgotten. Their small excavations and pits are found all along the lines of outcrops of the quartz veins, and in many places the soil not usually more than two feet in depth from the surface to the bed-rock, has been carefully washed.

Their "races," the lines of which are now nearly obliterated, and the ruins of their aqueducts, made for the purpose of conveying water to the mines, are to be seen in some parts of this district. All these tend to show that the miners found remunerative employment in mining both in the reefs themselves and in the soils containing the *debris* and *detritus* of the reefs.

22. It is not possible as yet to indicate the reefs that are distinct from each other, to show on the maps those that are continuous. Any attempt to indicate the main lines of reefs from a superficial examination of the country must necessarily fail. Such can be done only after a proper survey has been made, and the position, the strike, and the dip of each outcrop ascertained.

23. Korambars have been at work washing earth by ground-sluicing north and north-east of Devalah, and in some places they have obtained rough gold, which indicates the existence of reefs that in all probability will yield well. In one place a "*leader*" was cut by the Korumbars, a portion of which showed gold, and, if approved of, I shall continue to prospect with the aid of the native miners in order to discover the auriferous reefs.

24. The Korumbars have been working lately near Needle Rock, and I have also commenced box-sluicing in the same locality. There was some delay in obtaining suitable timber for making boxes, but those that have been made will be sufficient for the purpose intended.

25. There are two quartz reefs at Needle Rock which I have examined, and which are shown on the key-map, and the proprietor of the estate has informed me that he has sought the permission of His Grace the Governor to name one the "*Buckingham Reef*" and the other the "*Chandos Reef.*"

26. I have purposely omitted to this progress report all reference to the mineralogical facts observed, and other details which, unless instructed to the contrary, I propose to mention in my final report.

27. The weather during the past month has been favourable, and it continues fine, and I have hope that I shall make rapid progress with my field-work. On Saturday next, the 9th instant, I propose to go down the Carcoor Ghaut, and to visit the mines near Murdainy. It is said that the season is now favourable, and that any delay might result in my finding it difficult to induce persons to accompany me to a locality which is reported to be unhealthy in the succeeding months. I trust that this proposal, though interfering to some extent with my work here, will be approved of.

28. I continue to receive information and cordial assistance from every one, resident in the district, who is aware of the nature of the work I am engaged on, and it affords me pleasure to state that Mr. Thomas Laing, the Quartz Miner, and Mr. G. E. Withers, assistant, perform their duties to my entire satisfaction.

29. On Thursday, the 21st October, His Grace the Governor was pleased to inspect numerous specimens of auriferous quartz obtained from the Alpha Mine, and to observe also the method of testing the stone by amalgamation. On the same day, His Grace visited and examined the reef at that point where the rich quartz has lately been discovered.

On Friday, the 1st November, those interested in mining were honored by His Grace's visit to Needle Rock, where gold was got both by box-sluicing and ground-sluicing.

30. On Saturday morning, the 2nd November, I had the honour to take His Grace's wishes respecting the mode in which I should conduct the investigations I have been appointed to make, and venture to entertain the hope that the final result of my labours may in some measure obtain His Grace's approval.—

OOTACAMUND, Dec. 9.

A CORRESPONDENT writes to the *Madras Athenæum* "The residents in this district, as S. E. Wynaad is now in the limits of the same, take considerable interest in the question of gold mining. We gather from the public prints that the *Madras Athenæum and Daily News* does not look at this enterprise in the sanguine manner that others do. Having had unusual opportunities of inspecting the Wynaad gold reefs and their outturn where marked, I have come to the conclusion that a company with a large amount of capital should make a good thing out of quartz crushing in S. E. Wynaad, but that an enormous amount of capital is required to crush with profit, as the gold is, as a rule, thinly distributed over a large bulk of stone—the gold is generally almost invisible. So that peculiarly expensive machinery is required, not only to extract the gold, but to retain it when extracted. The gold is much mixed with other metals and the separation of it from them is difficult. All "surface gold" (with collection) has been long since picked up by the natives of the land. "Washing for gold" cannot, therefore be profitably carried on. I observe that Mr. Brough Symthe is reported to have found reefs which yield at the rate of 204 oz. 11 dwts. 16·7 per ton. I think you are right to call this a ridiculous yield per ton of stone; a ton was not crushed to get this yield—a piece of stone with a quantity of gold in it was chipped off and weighed—and the calculation was made as if a whole ton of quartz had been crushed, and 204 oz. 11 dwts. 16·7 of gold had been found scattered over the ton. But even had a ton been crushed, and so much gold found scattered over it, the test of the capability of the reef would not be a sound one. At least 1,000 tons of quartz should be crushed and the average struck to ascertain the correct average yield of a reefs. The Companies which have been working for some years have crushed in the aggregate over 1,000 tons, so that there should be no difficulty in ascertaining the correct average yield. I have just seen 7lbs. of clean coffee taken off a tree in this district, as there are 1,200 trees planted to the acre there, the owner of the estate might boast that his estate yields at the rate of 8,400lbs. per acre, *i.e.*, nearly 4 tons per acre! But alas the other 1,199 trees have yielded in this acre so miserably, that the aggregate amount of yield from them is under 300lbs. Such being the case, would the proprietor of the estate be justified in advertising his estate for sale as yielding at the rate of 8,400lbs. per acre—because one tree has yielded at this rate? I fancy the said proprietor would be much laughed at if he published the assertion, so I quite agree with you that it is simply ridiculous to assert that your gold-fields yield at the rate of 204 oz. 11 dwts. 16·7 grs. per ton of quartz, because a chip of quartz yielded so much gold; had that said chip weighed 2·240lbs. instead of 4lbs., the yield of gold would have been 204 oz. 11 dwts. 16·7 grs.

Exaggerated statements of this nature will bring contempt on us—but the careful examination of the Wynaad gold reefs which I have personally made, leads me to the belief that a truthful assertion of unvarnished facts will do much good—and will bring capital into our district to work our reefs on the large scale which can alone ensure their remunerating capitalists.

If the yield is now exaggerated—a reaction must, sooner or later, set in—and our last state shall be worse than our first—a panic will arise and capitalists will be frightened from the safe investment, gold mining, *i.e.*, "quartz crushing" in S. E. Wynaad really does present.

A PEKING correspondent corroborates the report that Li Hung-chang has contracted with Mr. Arnold Hague, of New York, an able geologist and mining expert, for the purpose of prospecting for gold, silver and other minerals in the north of China. This he says has been effected on the suggestion and through the efforts of the American Consul and Vice-Consul at Tientsin. Mr. Hague is now in Tientsin, and will shortly take his departure for the mining regions. Our correspondent finds in the development of the resources of China the panacea for Chinese emigration to California.

AMERICAN PETROLEUM.—The total export of American petroleum from 1861 to, and including 1877 (16 years) is given at 442,699,968 dollars custom house valuation. From the best sources of information there are at this time 10,000 oil wells, producing and drilling, which, at a cost of 5,000 dollars per well, would make an investment of 50,000,000 dollars in this branch of the business. Tankage now existing of a capacity of 6,000,000 barrels cost 2,000,000 dollars and 7,000,000 dollars, have been invested in about 2,000 miles of pipe line connected with the wells. The entire investment for the existing oil production, including purchase money of territory, is something over 100,000,000 dollars, which amount cannot be lessened much, if any, for as wells cease to produce, new ones have been constantly drilled to take their place.

The Planters' Gazette.

TEA.

THE endeavours of Mr. Burrell and others to place pure Indian teas within reach of the general mass of consumers in Europe, and to educate, so to speak, the public taste for unmixed Indian teas, will make it less and less necessary for agents and brokers to urge the managers of our tea estates to manufacture the great bulk of their teas into "rasping tea."

To manufacture a "rasping tea" means to sacrifice all delicate aroma, all fine finish, in fact all that constitutes a "fine tea", fit for general and immediate consumption, in order to make a "bitter tea", that is unfit to be drunk by itself, and only serves as an admixture to low class China teas, without which they would probably not be saleable. It is a matter of congratulation that in spite of this great demand for "rasping tea", there is still sufficient fine tea turned out in India to sustain the good name, Indian tea has been making for itself, and as the demand by consumers for pure

Indian teas is increasing now rapidly, the evil of deliberately manufacturing an inferior tea from good leaf, will, no doubt, find its own remedy. Managers cannot be blamed. They as a matter of course, must comply with the instructions they receive from the agents. In manufacturing "rasping tea," the process of fermentation is checked untimely, and the leaf is partly fired, the result being a strong biting tea, which may perhaps be termed a kutcha tea,—such a tea however as the brokers want, but not an article that will do credit to India should it come pure to the consumer. As a rule however such tea does not reach the consumer, except as a component part of a mixture, consisting of perhaps one-part of this tea and six of China Congou or inferior Souchong.

According to official returns, the total area of land under tea cultivation, in the year 1876-77 (these returns are inexcusably late), amounted to 145,685 acres, showing an increase of nearly 21,000 acres over the recorded acreage of the previous year. We suspect, however, that some portion of the increase exists on paper only, and is due to imperfect returns in the year 1875-76. Assam shows up for 102,711 acres, Bengal returns 30,242, the North-Western Provinces 4,709 acres, the Punjab nearly the same, and Burmah ends the list with a solitary plantation of 150 acres, situated near Akyab. Nearly half-a-million acres of land have been taken up for planting, but are not yet planted, and a good deal of this will probably never be planted, being either unfit for cultivation, or reserved for the supply of timber and fuel to the plantations.

A third edition of Lieut. Colonel Money's work on "The Cultivation and Manufacture of Tea," has recently been published by Messrs. W. B. Whittingham & Co., 91, Grace-church Street, London. The body of the work is an essay for which the prize of the Grant Gold Medal and Rs. 300 was awarded by the Agricultural and Horticultural Society of India, in the year 1872. The book has since then been greatly enlarged and corrected by the experience of the past six years.

We give prominence to the following from the *Indian Tea Gazette* :—" Speaking of the necessity for the production of teas with the requisite quality and flavour to suit the taste of the English market, it cannot be too strongly impressed upon agents and managers that it is essential to pay more and more attention to the adequate manuring of the land. Poverty of soil means, we know, in many cases, poverty of the proprietor ; and it is not, of course, always easy for an owner to expend what he would desire to do in the way of enrichment of the soil. But seeing that too often inferior quality is due rather to exhausted soil than to imperfect cultivation or manufacture, and that where the former is the case, the only profitable remedy is judicious expenditure in the improvement of the land, it will prove short-sighted policy if every effort be not strained in this direction where the fact of the necessity is at all apparent."

It is said that the mosquito blight this season has proved a terrible pest, and the loss to proprietors in consequence has been most serious. Many promising estates this year have proved short 25 to 30 per cent. of their outturn from this blight.

A NEW ENEMY TO THE TEA PLANT.

Among the pests of the tea plant may be reckoned an apparently new insect, in the form of a caterpillar, which has lately shown itself on an estate on the Nilgiris. The owner of the estate experimented on a few of them, picked off his trees, and the following are a few particulars :—

(1.)—The caterpillar is about an inch long with five pairs of legs in addition to a pair where the body points off at the stern.

(2.)—It has a small cream-coloured head with a pair of minute black eyes, and has the power of drawing in its head, which it does when it comes into contact with any suspicious object.

(3.)—It is of a bright salmon colour, growing to a pinkey colour on the stomach. It is marked with one, and in some cases with three, black stripes down the back. Those having three stripes are, to all appearance, the older insects.

(4.)—Each insect has, on its back, a number of protuberances which correspond to the number of its legs, and which taper to a minute point. This is the most notable point of physical peculiarity, for through each of the protuberances the little creature emits a drop of bright transparent fluid as soon as it is touched on the back with a straw or stick ; and when it does so, it looks as if it has so many drops of dew resting upon it.

(5.)—It feeds voraciously upon the tea leaf, and in four or five days, half a dozen have bared a large bush of every leaf. They do not, however, touch the young buds, for the reason, probably, that there is more of tannin in them. This, however, is merely conjecture.

(6.)—The owner of the estate on which the caterpillar was found kept also a few in a bottle to watch their habits and development. Of the small number of five insects which were placed in a tart bottle with a perforated cork, and a small supply of tea leaf, frequently changed, four died and dried up against the side of the bottle, and only one underwent a metamorphosis, and has been kept in a separate phial without any further change being noticed for more than three weeks. It located itself before the change along the centre of a tea leaf on the upper side, and drawing the leaf into a fold, spread over itself a covering of a brownish color and of the consistency of a dense cobweb. It has remained in that state ever since.

(7.)—The insect when alive crawls by folding its body up and using alternately the front and back halves of its body to seize the branch along which it travels.

(8.)—Wherever it crawls it leaves a web behind it, in the same way as many caterpillars do, but the web it pays out is so strong that it requires some pressure to move or break it.

(9.)—The body of the insect is very tough, and when shaken off the tree it was difficult to kill even by rubbing with a stick, so that each insect had to be cut in two with a knife.

(10.)—The drops of liquid which it casts out through the pores on its back are also of a property which causes a cobweb to stick to anything to which the liquid attaches.

Probably some scientific people could throw light upon the nature of the insect and tell us if we are to look for a new pest in this shape, or whether it is an evil which is not likely to spread and assume ruinous proportions. A bottle full of these insects were submitted to the Commissioner of the Nilgiris, who was kind enough to promptly send them on to the Board of Revenue, who have science more ready to hand and are better able to help to determine the nature of the pest.

TEA IN CEYLON.

Much as writers on the subject of tea cultivation may differ on some subjects, they are at least agreed on the matter of altitude, and, indeed, it needs no practical acquaintance with the subject to understand that as the tea planter looks for his crop from repeated flushes of leaves, those flushes can only be obtained under circumstances favourable to a free development of vegetable organisation. This cannot take place in a region of continued cold with a low rate of rainfall : frequent showers and a tolerably high temperature, without being of a too forcing character, constitute the conditions most favourable for a succession of flushes. It has been laid down as an axiom by tea planters of experience, that the plant may be cultivated with profit within a range of several thousands of feet, and that whilst a high altitude gives quality, a low elevation is favourable to quantity. To what extent this rule holds good in Ceylon, and how far the experience gained in Assam may be applied to this island, are points which are yet open to discussion.

There is one matter, however, upon which we believe there is no room for doubt. The fact is indisputable that the soil of Assam is far superior to most of that to be found in Ceylon. The Assam plantations have been formed out of forests, the soil being a rich vegetable loam, free from stones and gravel. This well established fact should induce caution on the part of any who may be contemplating the planting of tea on land whereon coffee has ceased to be productive ; at the same time it may be well to bear in mind the opinion of agricultural experts who declare that, although land may have been exhausted of the elements necessary for the support of one variety of plant, it may yet contain the essential constituents of food for other growths. This point will be put to a practical test before very long, as there are at the present time portions of abandoned coffee estates under tea cultivation in several districts. Time alone can determine if the quality of the leaf produced be satisfactory, and whether such soil will continue to yield flushes sufficiently abundant to be remunerative.

To what extent aspect, soil, rainfall, and altitude will together or separately affect the quality, yield, and durability of tea plantations, has yet to be ascertained. The great variety of conditions under which tea is being cultivated in Ceylon, will, before many years shall have elapsed, supply us with such data as shall shew, beyond

doubt, what are the conditions favourable to the profitable cultivation of tea in Ceylon. That tea may be grown in this island, and exported at a price or prices that will leave a profit to the grower, we do not for a moment doubt, and that, too, on spots where it would not be possible to grow coffee profitably. A tea may be produced inferior in quality to that grown on other plantations, yet from local circumstances in its favour, it may give a profitable return to the proprietor. It remains to be seen how far the advantages we possess in cheapness of transport and certainty of labour, will help to counterbalance the undeniable gain to Assam of great richness of soil.

Tea growers must not, however, forget that there is much more necessity in the production of a good marketable article, than the mere cultivation of the leaf. Much depends on its manipulation, both in the first stage of firing and rolling, and in the after preparation of the leaf for packing. There are tea plantations in the close vicinity of Nuwera Elliya and the Wilson Plains, at an altitude of 6,000 feet, and in a comparatively dry climate : there is another on the north-west face of the Rambodde Pass, at an altitude probably of 5,500, but with abundance of moisture : there are estates again in Upper Hewahetta as high as 4,000 and 5,000 feet, but with a north-easterly aspect : there are tea plantations in Lindula, in Ambegamua, Dolosbagie, Yacdessa, and Rakwane, ranging between 2,000 and 3,500 feet, and there are again estates of tea on the Avissawella and Peak ranges not more than 500 feet above sea level. It has yet to be seen how it will fare with all of these in yield, in flavor, and in durability. But all will equally need the care and skill of an experienced manipulator.—*Ceylon Times*.

INDIAN TEA-MAKING, &c.

To the Editor of the Produce Markets' Review.

SIR,—The usual custom of plucking in carefully-managed gardens is as follows :—The flush, for the two first flushes, is allowed to run to five leaves, of which only three are taken with the stalk, at one pluck. A portion of the fourth leaf is also sometimes gathered at the same pluck, but this bit of a leaf is often taken separately, at a second pluck, or move, of the hand. The piece of the leaf that remains on the bush is left to nurse the succeeding flush. The fifth leaf is left on to nurse the tree, for the sap does not perceptibly circulate in the leaves of the preceding year, and some portion of refined sap must return downwards to form new wood. By circulating through the leaves, the nature of the sap is altered. If every leaf were taken off, the new wood would become spongy and porous, and the tree in a few years would languish and look old. The old sap melts and returns ; the new sap rises by the action of the sun through the outer bark. In the root it appears to be only weak sugar and water , as it rises, it evaporates and becomes thicker, till it reaches the bud, which it occasions to grow.

The half leaf alluded to above having been separated from the stalk, will not easily roll, and often will not colour black (because it is separated from the stalk), and is called by us planters red leaf or fannings, while if it colours black it is called Broken tea. The twig with the three leaves on and the broken leaf are rolled together ; the different qualities, Pekoe, Pekoe Souchong, Souchong, and Broken Tea, are separated afterwards by sieving. When the leaf is put over the fire to dry it is red, the same colour as after infusion, but as it becomes dry it assumes a black hue. To colour the leaf black (in drying) it must be rolled with the stalk. Not so with green tea . then the leaf ought to be separated from the stalk, and the stalk must not be rolled with the leaf, or it will bruise it, make it red, and then it would dry black and not green. Respecting the third, fourth, and fifth flushes or harvests, the flush is only let run to four leaves, of which three-and-a-half are taken as above. There are many pluckings, three to each harvest—the early, the middle (the heaviest crop), and the latter shoots. The stalks in China tea are for the most part winter prunings, added afterwards : they are known by the clean cut of the knife, and their hardness. The true stalk of the flush is very, very, delicate, or the small delicate women and children of India, with hands more delicate than any of our women, could not pluck it. Bear in mind that it is plucked, not picked ; that is, it is seized or held between the soft parts of the first finger and thumb, and if not delicate and soft, would not come away, indeed, does not do so, if the harvest is a few days too old. The harvest is often gathered in torrents of rain, which men in this country would refuse to work in.

Pekoe in Chinese is "hairy leaf," and is the top bud. There are four to five harvests in the year, but every harvest does not give a hairy bud at the top of the twig. The first flush rarely gives it, as there is too much sun, which opens the bud too quickly ; nor do old trees always give it. In our English nomenclature, Pekoe means the top bud and the top leaf ; Pekoe Souchong, the leaf between the Pekoe and Souchong, the second on the stalk ; in fact, it means neither Pekoe nor Souchong. (Carefully sieved leaf ought to have no Pekoe tips.) Souchong means the third leaf on the stalk. If the Pekoe has few flowery tips, it is absurd to expect to see any in the Pekoe Souchong. To have flowery Pekoe, we must have a suitable season for it—sun, mist, and rain, in equal proportions. The red liquor of all black tea is made by brusing the leaf in the act of rolling (just the same as an apple, when bruised, turns red inside, although the skin is not broken), and the act of getting or becoming dry, no matter how, occasions it to assume a black look. If the leaf is rolled too hard, the juices run out, and quickly lose their flavour, become sour, just as the juice of an apple becomes cider. In the act of rolling, the red juices of the leaf roll over the white silver tips, and this makes the tips red, called Orange Pekoe, and the leaf at the side dries black. Orange Pekoe shows that the tea has been rolled properly. Flowery Pekoe means bright silvery tips, neither flower nor blossom.

A PLANTER.

Cheltenham, October 17th, 1878.

THE INDIAN TEA INDUSTRY.

THE cultivation of tea in in the British dominions is becoming a rapidly extending industry. Two small parcels of Ceylon tea were sold at the public sales this week in London, and realised a fairly satisfactory price. For a first effort the result was hopeful, although it is said there is much room for improvement in the quality. Whether tea cultivation will ever rival that of coffee in Ceylon, it is impossible to predict, as the industry is quite in its infancy. Capital, however is being raised, and we believe that a Ceylon Tea Company is being established with every prospect of success, although possibly in these times of dear money and general depression, the most favourable moment may not have been chosen for the launching of the Company.

The progress made by Indian tea is remarkable. It is becoming largely used in England, and it promises to be in future a serious rival to the Chinese productions. In 1873 only 18½ millions of pounds weight were imported into Great Britain from India, against nearly 32 millions in 1877. At the Paris Exhibition Indian tea, especially under the auspices of Mr. Burrell, has taken high honours, and it was judged superior to the Chinese teas. Mr. Burrell has been very successful in making Indian tea known in Europe. The gardens of Assam, Cachar, Chittagong, and the Neilgherries, and a number of other districts, are becoming celebrated throughout the world for their productions. No doubt the industry has suffered variations of fortune since its commencement, and its very existence has been threatened by the inexperience and want of knowledge of those who so eagerly went into the enterprise, and made haste to be rich with the proverbial result. As Colonel Money points out in the prize essay,—which we are glad to see has reached a third edition, for it is full of practical information, and deserves to be studied by every tea-planter,—a number of people of various occupations engaged in tea cultivation, for which they were not suited, and naturally failed to do any good. Tea cultivation, like everything else, requires special knowledge and experience. A proper amount of labour is essential, and this is now being obtained by the Assam tea planters from different parts of India. Considerable difficulty was also found in the Government regulations for the sale of waste lands. The Government might have been expected to give a more active and practical support to such a promising industry as tea. Other industries have probably been favoured with direct, or perhaps equally valuable indirect encouragement, and it is sufficiently recognised as a general principle by the Indian Government that the resources of the country should be developed, or at least that the first attempts at development should be made, with the assistance of the Government. Tea cultivation is of course now able to stand on its own merits, although a liberal basis might very well be admitted for the granting or leasing of Crown lands, and the Government ought to be sure of its own title to the lands it sell before putting them up to auction. For capital to be expended, security of tenure is required, and Colonel Money seems to think that this essential for an extensive and successful industry is not satisfactorily provided for under the present arrangements. The Government have also caused dissatisfaction by their stringent regulations regarding coolie labour. Each coolie brought to the tea gardens costs Rs. 30 ; and there are the expenses of housing the people, and supporting them when they cannot work ; and if the cooly dies, the planter loses of course the whole of the money expended in obtaining his services. This labour difficulty is one that will cure itself in time, for, with all the dense population of India to draw upon, a sufficent emigration could surely be secured that would satisfy the needs of the tea districts. The sugar planter in the West Indies has to spend at least £20 for each labourer he obtains from India, and to take all the risks besides of a long sea voyage, and of mortality among the people. In comparison with these conditions, the Assam tea planter enjoys facilities for obtaining labour which may be said to be perfect in

their way. He is, however, bound to produce as cheaply as he can. There is not a practically unlimited demand for tea. With a consumption that is not capable of an unlimited expansion, the hope of the Indian tea-grower must be in a successful competition with the Chinese producer, and this can only be brought about by sending to market tea of equal excellence, with that from China, but produced at such a cost as to allow a greater margin between profit and loss. That the struggle as to relative cheapness of production is becoming keener, the failure of the Japanese tea-growers to successfully compete against other sources of production is decisive proof. Goodness of soil, fully utilized by proper agriculture, thoroughly appropriate climatic conditions, plenty of labour and economy in using it, careful attention to quality and taste, and advantage of transport,—these are the mainsprings, both natural and artificial, of the Indian tea industry, and we may hope to see the tea gardens of India increase and multiply until the industry becomes sufficiently important to be reckoned as one great factor in the prosperity of India, and one unfailing security against that evil of national bankruptcy which it is the gloomy fashion of pessimist writers on Indian affairs so confidently to predict.—*Planters Gazette*.

COFFEE.

A CORRESPONDENT has sent a Ceylon contemporary a Liberian coffee leaf measuring 15 inches by 7 inches—probably one of the largest specimens ever seen.

The Mysore Planters' Association has applied to the local Government for the loan of the services of Mr. Harman, of the Experimental Farm, for a few weeks, that he may be able to give his opinion on that much vexed question—Coffee leaf disease.

SULPHUR AS A REMEDY FOR LEAF DISEASE.

A CORRESPONDENT, whose opinions are entitled to great weight, Mr. Morris, of the Royal Botanic Gardens, Peradeniya, Ceylon, writes :—

As there is now some indication of a trial being given to sulphur as a means of checking leaf disease, it may be of use to planters to have their attention drawn, through the columns of the *Observer*, to the "extracts and correspondence relating to the process of sulphuring diseased plants" which form the appendix to the accompanying report.

Sulphur seems everywhere the recognised specific for fungoid pests, now that (thanks to the labours of the scientists who have lately been so soundly abused) it is pretty well established that the *Hemileia vastatrix* in one stage of its existence, at least, is superficial, it is therefore within reach of such treatment as that applied to the *mildew* of hops and the *oidium* of the vine. If a serious attempt is made in Ceylon or a large scale, and extending over two or three seasons there is no doubt something satisfactory will be obtained.

I was reminded to-day by Dr. Thwaites of a astrong proof of the efficacy of sulphur in checking fungoid attacks in the case of the potato disease. This disease is caused by a fungus (*Peronospora infestans*) which like the *Hemileia* during one stage of its existence has a superficial development, that is, it is found on the stem and leaves of the potatoes before it penetrates the intercellular tissue and gives rise to fruit spores. Now in the neighbourhood of Swansea, where the air is charged with sulphurous fumes from the large copper works of that district, the potato disease is hardly known, and I have often noticed that the potato was the only vegetable which could be successfully grown within a certain area there.

If sulphur were applied in May, during the rainy weather, and carefully dusted over the stem, branches, and leaves of the coffee trees it is quite possible it might check the severity of the attack which comes on in June, July, and August. Again, say in September and October, when the fungus has fruited and the spores are lying in thousands on the ground ready to germinate and cover everything with their thread-like filaments, a good sprinkling of sulphur on the fallen leaves and everywhere round, might destroy the spores and prevent the filaments from again reaching the trees. These seem to be the best seasons for operating ; but even now it is not too late to apply sulphur to the stem and branches and thus kill the filaments that are probably luxuriating there under the influence of the present moist atmosphere. It is quite a mistake to think that because there are no fruit spores, there is no leaf disease. A microscopic examination of the branches, and leaves would, in April and May or almost at any time in the year before the spores appear, reveal such a development of mycelium or thread-like filaments of the *Hemileia* as would convince the most sceptical of its existence.

By all means give sulphur a fair trial—nothing promises a more satisfactory result if thoroughly and systematically applied.

The passages in the appendix to Mr. Cooke's report, sent to us by Mr. Morris, are as follows :—

Extracts and Correspondence relating to the process of sulphuring diseased plants.

"Wherever white fungi appear, at least where the fruit is superficial, sulphur may be applied with great advantage. As regards the peach mildew, practice had taught its value long before the grape mildew was thought of, and it will be found equally efficacious in the case of strawberries and other plants which suffer from similar attacks." *M. J. Berkely in Gardener's Chronicle, 1856, page 502.*

In practice it is found that the easiest, most economical, and at the same time the most effectual mode of applying the sulphur is by a common dredging box at the end of a long pole. Little at present has been done with solutions, but we should strongly recommend trial of Grigson's mixture especially in the later stages of the disease, as more speedy in its action. In all cases, however, the grand point is to watch the first indication of the mould, and apply the remedy at once.—*Gardener's Chronicle 1854, page 595.*

The composition of Grigson's mixture, recommended in the case of the vine disease, was the following : One pound of flower of sulphur, and an equal volume of fresh slaked lime, to be boiled for ten minutes in an iron pot in five pints of water, so as to give four pints of clear solution. This is to be mixed with one hundred parts of water, or to such other strength as may be found most efficacious, and applied with an engine.—*Gardener's Chronicle 1854, page 595.* [We should think that the mixture of lime and sulphur dusted on to the trees before or during rain would answer the same purpose.—*Ed., C. O.*]

In reply to applications to hop-growers in Kent for information as to the process in practical use amongst them, the following has been received ; "In answer to your question as to the use of sulphur for the cure of mildew in hop plants, I beg to inform you that 'flowers of sulphur' are usually employed for this purpose, which are the best sublimated sulphur. Some hop-planters, however, prefer *sulphur vivum*, or black sulphur 'soufre crut, which is, I believe, crude sulphur melted, allowed to cool after stones and other foreign substances have been disengaged, and then broken up. This is used largely in France in the vineyards against the *oidium*, it is heavier than the flower of sulphur and there is therefore, more difficulty in it application.

Sulphur is put on in hop-gardens at the rate of from 40 to 80 lbs. per acre there being about 1,100 hop-plants to an acre on an average ; with a sort of travelling winnowing machine, with a swiftly revolving fan, which blows the sulphur over the plants, as it is drawn between the rows by one horse. The rows of plants are arranged with regularity at distances of from 6 feet to 6 feet 6 inches apart, so that the sulphurator travels easily between them, being about 2 feet 8 inches in width. Their height is from 11 to 18 feet, so that the sulphurator, whose blast or pan from which the sulphur is expelled is about 3½ feet from the ground, covers the greater part of their bine and leaf surface with the fine dust.

The operation should be performed at night when the dew is falling, or after rain, that the dust may adhere to the plant, it is done twice, or even three times, but care must be taken not to apply sulphur after the flowering of the plant. As coffee plants are not higher than from 6 to 10 feet, and as I imagine not planted in regular rows, a dredge, and by hand, would probably be the best machine to use for putting on the sulphur. There are small hand machines with fans, as used in green-houses, that might be made, available.

May I be permitted to refer you to a paper upon Hop Cultivation, written by me in the sixth volume, second series, of the Journal of the Royal Agricultural Society of England, which fully describes the process of sulphuring."—*Charles Whitehead, Maidstone, Kent.*

As one of the oldest planters I have used sulphur for the cure of mildew, or as it is generally called mould by hop-planters, for many years. At first *sulphur vivum*, or refuse sulphur being cheaper, was used, and I believe I was the first planter who used the flowers or finest sulphur, which has been found the best, as it adheres more closely to the plant, and I believe is as cheap, from there being less waste. It is not used till the hop is in burr or blossom, or till white spots are seen on the leaves, though many planters almost always use it for precaution. The plant should have moisture on it to make the sulphur adhere, when it requires less. It is of little use applying it in dry hot weather, and thus, used will sometimes blister, and it requires some knowledge when and how much to apply. It is applied by an instrument drawn by a horse, which throws the sulphur over the plant, and as the coffee plant does not grow so high as the hop, and is planted as regularly, that may be easily done. One caution may be necessary. Hop-planters seldom use sulphur when the aphides or lice are found on the hops, as from a cause unknown the plant generally goes into what is termed a black blight.—*F. B. Eloy, Maidstone.*

In reply to yours received yesterday respecting the use of sulphur on growing hops. The way of using it is to put it on dry, not as a solution. Flowers of sulphur is used, and sometimes *sulphur vivum*, or black sulphur but the former would be the better for vines, and I should think for the coffee plant, but I know nothing of the habit of the latter. For hops we have a machine to throw it over the tops of the hops, and generally find it effectual.—*George White, Maidstone.*

In reply to your letter I beg to give you the following information regarding the application of sulphur to hop bines. The preparation of sulphur, which I prefer is the flowers of sulphur, but some hop-growers use a preparation called *sulphur vivum*, which costs less per ton, but which I believe is as dear in the end, and of less power as regards the mildew. My sulphur is applied either early in the morning when there is dew, or else on a still evening, but some hop-growers apply it in the day-time, when the sun is shining, which I consider leads to a very great waste, as when the hop leaves are dry, such a small proportion of the sulphur adheres to them. The sulphur is blown from a machine which is drawn by a horse up and

down the hop alleys. These machines I doubt whether they would be applicable to a coffee plantation, as I apprehend the coffee plant does not grow any height compared with the hop bine, and probably is not planted in rows six feet apart as the hop hills are. There is a hand machine which has been made for me which would be more likely to answer for use in a coffee plantation than the horsemachine, but failing this, a dredge for dusting by hand might be used. I apprehend the coffee planters do not labour under the same difficulty as the hop-growers as regards insects. Often hop-growers in trying to save their crop from being destroyed by mildew are drawn into as bad an evil, for if there are only a few aphides on the leaves, the use of sulphur leads to so great an increase of them as materially to injure both crop and quality. It seems extraordinary that this should be the case, but numbers of hop-growers can bear me out in what I say. I know of no one who uses a solution of sulphur.—*E. J. Goodwin, Wateringbury.*

At the very outset, Mr. Berkeley suggested sulphur as a remedy for leaf disease. Mr. Cooke, however, the other great authority on fungi, in the body of the report from which we have extracted the appendix on sulphuring, while strongly recommending sulphur as a remedy for another fungus, the "black rot" of Mysore, expresses doubts of its efficacy in the case of *Hemileia vastatrix*, thus :—

The means to be adopted for getting rid of a pest of this nature must necessarily be simultaneous on the part of all the planters, or it will only be temporarily banished from one estate, to be soon revived by the transportation of the minute spores through the air from estates on which the parasite may be permitted to flourish. There are features in the character and mode of action of this fungus which leads to the belief that the application of sulphur would have the same beneficial influence that it now has in the hop-gardens in checking the hop disease. When sulphur was first proposed for the hop it was with difficulty that the planters could be prevailed upon to adopt it. The opposition which the practice encountered was strong at the time, but experience having proved its undoubted value, it is now universally adopted. Although it is improbable that sulphur would be of any use against an endophyte like the coffee leaf disease (*Hemileia*), the "rot" is very different, and would submit to a different treatment. There is no doubt that every diseased leaf picked from a plant and burnt, diminished the" sources of future injury by so many depôts of undisseminated spores.

Again :—

Various opinions are expressed in the reports as to causes and treatment of the disease, on which it is difficult to form an opinion, and unnecessary to offer comment, further than to call attention to the fact that faulty drainage, stagnant water, and partly decomposed vegetable matter in the soil, are all favourable to the development of fungi, and determined to the healthy condition of the plants. It is doubtful whether sufficient precaution is always taken, either at home or abroad, that the soil about the roots of growing plants should not be contaminated by the mycelium or "spawn" of fungi, which is always to be found amongst partially decayed vegetable debris.

The specimen of soil sent with the leaves now examined is largely impregnated with mycelioid filaments. The partly decomposed fragments of twigs are so many centres from which the mycelium radiates in all directions. The appearance of the soil seems to indicate such an amount of stagnant moisture as would foster "root fungi," and prove detrimental to the growth of healthy and vigorous plants. Although some of this soil has been placed under experimental conditions, with the view of obtaining more certain and definite data, the result could not be ascertained so soon as would be required for this report. If any fact of importance should be evolved, it will be made the subject of a supplementary memorandum.

Fungi of the character of the *Hemileia* are not likely to be beneficially affected by the application of sulphur. Picking the leaves as soon as the fungus makes its appearance, and burning them, may, if perseveringly pursued, be of service. In Mr. M. D. Meppen's reply (see "Tabular Statement," page 11,) he states that : "last year he stopped its progress in a small field of young coffee by picking off the affected leaves. As soon as he observed the disease amongst the plants, he put in children to pick off all the affected leaves, which were collected in baskets and afterwards burnt. This stopped the disease on that field, as it did not appear again ; the young plants soon recovered, and became in fine condition." This is however, a tedious process, and not so easily accomplished when the trees acquire a larger size.

LIBERIAN COFFEE.

(Proceedings of the Madras Agri-Horticultural Society.)

READ letter from Deputy Surgeon-General Shortt, dated the "Retreat, Ercaud, 30th September 1878, forwarding the following report on his Liberian Coffee plants, and asking for a few plants of Pithecolobium saman.

"LIBERIAN COFFEE.—I received two plants from the Agri-Horticultural Society, Madras. These were sent to me from Bangalore, through Colonel Benson, and arrived here on the 21st October 1875. They were about 6 inches in height, looked sick and lanky, one having four and the other two leaves. They were planted out on the slope of a hill-side a little over 4,000 feet above sea-level, with a north eastern aspect under the chequered shade from some jungle trees in the vicinity : and in the midst of othe coffee which are 6 to 8 feet apart. A note was made monthly of their progress. But as there was not much to record during several months of the year, I will only here notice such months in which any preceptible change was observable.

"The plants continued stationary, and on the 6th December of the same year, No. 2 put out two fresh leaves. In February 1876 both plants looked dull, and during the following months of March and April were attacked with the leaf disease. In May No. 1 died down to the level of the soil, whilst No. 2 continued sick with shrunken and decaying leaves. In June No. 1 threw a new shoot from the root-end below the soil, and No. 2 put out fresh foliage, and improved materially in appearance.

In July No. 1, that had thrown up a new shoot died away completely, whilst No. 2 was looking vigorous and healthy and had attained 15 inches in height at the end of August, although infested with the coffee bug, whilst the common coffee was free.

"In April 1877 this plant had attained two feet in height, but was looking sick with most of the leaves more or less corroded. It continued much in this state with little or no improvement till July, when it began to recover its health and had put on a strong and vigorous appearance. In the month of October, though looking healthy, the plant continued stationary, and in January 1878, it continued much in the same state. It stood the subsequent dry weather very well and it now stands 40 inches in height and has four primary branches, averaging between 7 and 8½ inches each in length, the first pair is given off at 22 inches from the soil, most of the leaves are imperfect having corroded away, but the remnant left is green and healthy. At the summit of the plant as well as at the end of the branches, a fresh pair of leaves have formed in each, the largest perfect leaf measures 8½ by 4½ inches. This plant is now a little above three years' old, on the 21st of next month it will be three years since it arrived here, and perhaps when it came up it was between two and three months old.

"I have given the plant no special care beyond that of keeping it free of weeds, and in June last it got two baskets of manure (equal parts of cattle manure and rotted vegetable matter).

"A few months ago I received three other young plants from the Society. These were immediately on receipt transferred to larger pots, and after a couple of months were planted out in the open in somewhat rocky soil, with a southern aspect at the same height ; after a while two of the plants withered away, and the third is now shooting up."

Resolved, that Deputy Surgeon-General Shortt be thanked for the report, and informed that this Committee will be glad to have further reports on the subject, and hopes that he will soon have better progress to communicate.

COFFEE PROSPECTS IN TRAVANCORE.

IT seems pretty certain that the present season in Travancore will be a very poor one, worse, if possible, than either of the two preceding years. The hopes raised at the beginning of the year by the good blossoming have been falsified by the subsequent failure of the berries. The crop has dropped in an immature condition from the trees and not more than a fifth or a fourth of the estimated crops will be forthcoming. On some estates the outturn will not exceed three bushels to the acre, and certainly very few plantations, if any, will pay expenses. This discouraging outlook is all the more distressing that it follows two very poor years already. Many a small capitalist has hoped on and tided on in the sanguine expectation of "pulling it off" this year, whereas all such planters will now be in a worse state than ever. The multitudinous small native planters who have sprung up from nothing like mushrooms, will collapse like mushrooms, and their estates heavily mortgaged, will not, in the present state of things, fetch the money advanced upon them. These men are turning hopelessly in all directions for the means of paying off their old debts and of carrying on their coffee works.

The South India Coffee Company are also feeling the gloomy outlook very severely. Not only do their own estates cost more than they produce, but the heavy advances to others have drained the coffers most unmercifully. The Company find that, in anticipation of a better crop than will actually be realised, they have allowed their clients to overdraw the value of the now estimated outturn. Consequently, they have been obliged, in self-defence, to put the screw on pretty tight, and to demand the repayment, at once, of the overdrawn amount. When the only hope of payment at all lies in the crops, and when the crops themselves are overdrawn, it is not easy to comply with the Company's demand on any terms whatever.

There is no ground for despairing of the ultimate and even proximate success of the Travancore coffee enterprise. The abnormal seasons of the last three years have thrown the coffee, root and branch, into an abnormal condition. The trees miscarry of their fruit by reason of the weakening influences of the past few years. They want tone, and this, we trust, they will soon get. The cycle of drought should have exhausted itself in the present season, and 1879 ought to inaugurate a cycle of bumper crops such as were seen seven or eight years ago, when within three years of planting the Rova estate paid all its previous expenses by its maiden crop, and left a substantial profit in addition. The comparatively low elevation of the Travancore estates is the cause of their ruinous failure when the rainfall is less than usual. This defect cannot be remedied except by the abandonment of the low coffee altogether, and this probably will yet have to be done. There is one ray of hope, though a heavy feeble ray, in the thought that a short crop may fetch higher prices through sheer scarcity of the article. We have not at present sufficient information with regard to this year's coffee produce of other countries to enable us to gain any solid comfort in this direction.

The heavily handicapped condition of the coffee enterprise in Travancore, to which we have referred on previous occasions, is now felt to be a very serious burden indeed. Land tax and export duty have to be paid on the produce of land which would not fetch its original purchase-money if put up to auction to-day. It would be an act of grace to remit the land-tax on all coffee land purchased within the last seven years, on land, that is, that has hitherto been nothing but an expense and a loss to its owner. The Government would lose something certainly, but this will happen in any case after such a year as the present. Those sanguine but impecunious individuals who "went into coffee" on borrowed capital and have been borrowing ever since will have learnt a wholesome lesson; while hopeful capitalists will buy up no end of coffee estates for a mere song. It's ill wind that blows nobody any good.—*Madras Times.*

SULPHUR AND BURNT LIME AS REMEDIES FOR LEAF FUNGUS.

On the effects of sulphur we have the following testimony from a planter of so much experience as Mr. James Blackett:—

Dotel-Oya Estate, Aranayka, 5th November 1878.

Dear Sir,—In your issue of last Saturday, you court enquiry on he application of sulphur, under the heading of "Cure for Leaf Disease."

The following is at your service. In November 1875, I applied 5 *cwts.* of sulphur to a little more than five acres of coffee, or at the rate of an ounce to a tree (patches of which had several severe attacks of leaf disease) mixed with artificial manures, spread evenly over the surface and thoroughly dug in to the depth of 8 to 12 inches with one-pronged diggers, and for the first year or two I could see no abatement of the fungus as the seasons came round; but during the last twelve months I could see an improvement, not very great, but a decided check, and I am now of opinion that the action of sulphur is slow and that it should be applied in larger quantities. I intend trying two ounces to a tree very soon.

There are a good many things to be taken into consideration with regard to the coffee, I have tried the sulphur on, such as the crops it gave before leaf disease was known and since then, and the treatment it had before and after, and present appearances with a crop of at least 8 *cwts.* an acre this season, all of which I have made fair allowance for in my own mind before forming an opinion as to the efficiency of sulphur; but I am apt to err like most mortals.—Yours faithfully,

Jas. Blackett.

Sulphur must be applied in much larger quantity than about 80 lbs. to an acre, before immediate and marked effect can be produced. Mr. Blackett's experience seems hopeful, however. Probably mixing the sulphur with acid or ammonia calculated to make it immediately soluble would be advisable. Good cow-dung would probably be a good vehicle.

We have several times adverted to the beneficial effects of lime, our latest reference being to the case of a planter who has found the application of burnt coral to some of his land followed by such excellent effect that he is determined to treat all his land after the same fashion. But even more than in the case of sulphur liberal applications of lime are necessary, and in the absence of railway extension the cost is in many cases prohibitory. Of the value of lime, however, there can be no question. Some of our readers may recollect a paper on the "Soil of Old West India Sugar Estates," by Professor Phipson, which we extracted into the *Observer* and commented on. Dr. Phipson traced much of the infertility of the exhausted soil to the absence of lime. That burnt lime applied to sugar land is followed with the best possible effect we have had fresh proof, in the account a Ceylon sugar-planter has favoured us with a visit to sugar estates in Penang. The estates were formed on mangrove swamps which were bunded and sluiced with reference to a rise and fall of tide, equal to 6 feet. Drains or rather canals were cut through the land so as to give facilities of water carriage. From our friend's description, we were reminded of all we have read of the sugar estates in Sir James Longden's former scene of Government, Demerara. After a time the canes on this land were affected by insects (*pou blanc*) and red rust, much to the diminution of the returns in sugar. But vast masses of comminuted shells were close at hand which Chinese were employed to burn. By means of the facilities of water conveyance, the estate was thoroughly limed, and all evil effects disappeared. It is true that specimens of the insects may still be found when sought for on the canes, ready, no doubt, to multiply and do mischief should the lime be used up. But there is no red rust and no diminution of the fair average yield of sugar. We are strongly inclined to believe that, were it possible to lime a coffee estate at the rate of 5 tons per acre, it would suffer little, if at all, from the effects of fungi, or grubs, or white bugs.

EXPERIMENTS IN COFFEE CULTURE.

In the Ceylon Legislative Council on November 20.—The Hon. G. A. Talbot, in introducing a motion "That the different species of coffee grown in the West Indies be imported and grown in the Royal Botanical Gardens of Ceylon," remarked that they all felt indebted to the Governor of Trinidad for the information as to the coffee grown there, which he had sent here. If those species could be developed and grown here it would be the means of increasing our large industry—the planting industry. There was a great deal of uncultivated land at nearly every elevation and with a great many different sorts of soil, but lately an impression had gone abroad that all the land available for coffee has been filled and that there is no more jungle which could be planted with coffee, and therefore a great deal of capital which would otherwise have come here, had been diverted. It was more than probable that if those different species could be introduced to the Botanical Gardens a great deal of land which cannot now be used might be planted with coffee. He therefore moved that those species be introduced to the Botanical Gardens at Peradeniya.

The Hon. J. P. Obeyesekera had much pleasure in seconding the motion made by the Hon. Member for the planters, especially as there was every probability that several species of coffee may be discovered in the West Indies that would be suitable for the lower elevations at the maritime districts of Ceylon. The fact that the Liberian coffee grows well at a low elevation afforded him every reason to suppose that fresh varieties can be obtained from the West Indies that will be equally suitable for the low lands here.

His Excellency said that there was only one point on which he would ask the Hon. Member (Mr. Talbot) to make an alteration, and that was to introduce the words "and Surinam, Dutch Guiana and Berbice." The English Colony of British Guiana was a very large coffee exporting colony at one time, but the coffee plantations were rooted up to give way to sugar plantations, which were more profitable, although the coffee was a very fair quality indeed. The coffee land there lay at water level, or even in some places below the sea level; there were not any high hills there.

The Hon. Mr. Talbot said he and in fact every one interested in Ceylon was very much obliged to His Excellency for the information which he had given them. He, therefore, inserted the words suggested into the motion.

The Colonial Secretary observed that the Government would have the greatest pleasure in complying with the motion of the Hon. Member

The Hon. Sir Coomara Swamy suggested that the words "Botanical Gardens" should be omitted and that "Ceylon" should be inserted in their place, as it might be found that the coffee would be found to grow better in other places than the Botanical Gardens.

THE INSECT REMEDY FOR LEAF DISEASE.

Sir,—In a recent visit to some estates in the lower coffee districts, I examined as many fungus-diseased leaves as I could, whilst walking through the various estates, and shall be very pleased to hear from others, that my experience was not an isolated one.

In Kadugannawa, on about one-third of the leaves examined, I failed to find any insect preying on the fungus, but on the remainder, there were as many larvæ feeding as would average 5 or 6 to a leaf; on several leaves there were 9 or 10, and on one as many as 26. In west Matale my experience was the same, only there the number on one leaf was as high as 34.

All the estates I refer to adjoined native jungle and chena,

The larvæ were all lively, and on most of the leaves had entirely eaten away many of the patches of fungus, leaving only round marks like stains.

I believe the larva to be that of a minute fly, as I saw several of the latter walking about on the fungus spots, apparently laying eggs; the fly is, I think, identical with one I noticed some years ago infesting the wild fig tree in the low-country, on opening the fruit of which I have seen hundreds if not thousands emerge from their prison.

If others in the low-country can corroborate my experience, I think we may have great hope that in the insect world we shall find at least one of our best allies for overcoming *Hemileia vastatrix*.

F. M. MACKWOOD.

Colombo, 16th Nov. 1878.

PORTER AS A CURE FOR LEAF DISEASE.

W. A. M. D. writes to a Ceylon contemporary:—"Referring to your paragraph, "cure for leaf disease," in the *Observer* of November the 2nd and the mention therein of the use of country rum in the preparation recommended by the correspondent to the *Gazeta de Noticias*, Rio de Janeiro, has re-called to my mind a fact which I saw some years ago on a large estate in Dimbula. The field of coffee round the bungalow had a very bad attack of leaf disease, but another gentleman and myself remarked that a few trees near the bungalow markedly stood out as having hardly a diseased leaf. A close examination showed that the drippings and washing which pass a lot of beer and porter bottles, must have been the cause. We therefore, to try the experiment, applied two bottles of porter to six trees that were affected and found that these trees recovered in a wonderfully short time. Of course we thought nothing more of it as the little item of cost stood in the way.

CINCHONA.

A RESOLUTION on the annual reports on cinchona cultivation and on the Quinologist's report is published in a recent issue of the *Calcutta Gazette*. The cinchona plantation consists of two parts—the older portion at Rungbee, Rishap and Mungpoo, in the valley of the Runjo; and the newer on the Sittong spur, and in the adjoining valley of the Ryang. The working of the plantation during the year 1877-78 was, on the whole, very satisfactory. The Sittong plantation was increased by 152¼ acres, and the older plantation by 97¾ acres. The total area of the former is now 242 acres, and of the latter nearly 2,000 acres. The Sittong plantation is still too young to yield a crop, but the crop from the older portion was 344,225lbs. of dry bark. During the year under review 706,600 red bark trees (*Cinchona succirubra*) were planted out, namely, 26,800 in Rungbee and Rishap, to replace the old plants uprooted in taking the bark crop, and 679,800 on new land—265,800 on Mungpoo, and 414,000 on Sittong. In addition to the red barks, 8,870 trees of a hybrid variety were planted on the Sittong division; this variety yields an excellent bark and promises to be very valuable. Efforts have been made to increase the cultivation of the yellow bark tree (*C. calisaya*), which produces the most valuable of all the medicinal barks; but owing to the difficulty of propagating the best varieties by seed, progress has been slow. The result of the year's operations with these plants has been only to increase the stock in the nurseries by 2,000 plants. The question of selecting other localities, where the climatic conditions are more favourable for the propagation of this plant than in Sikkim, has been separately submitted by Dr. King, and is under the consideration of Government. The crop of the year consisted of 341,060lbs. of red bark, and 3,165lb of grey bark, or 344,225lbs. in all of dry bark, against 207,781lbs. in 1876-77 and 211,391lbs. in 1875-76. The bark yielded in former years, *i.e.*, from 1869-70 to 1876-77, amounted in the agrregate to 529,017lbs., so that there has been taken from these plantations since their commencement no less than 873,242lbs. of dry bark. The Red bark crop was taken by the three methods of harvesting usually followed, namely, up-rooting, coppicing, and thinning :—

	lbs.
Up-rooting	[illegible]
Coppicing	[illegible]
Thinning	97,274
Total	[illegible],060

Ninety-two and a half acres of trees planted at distances of six feet by six were up-rooted and 176,625lbs. bark thus obtained, being at the rate of 1,909lbs. per acre. The land on which these trees were grown was not well suited for cinchona cultivation, and the outturn given above does not include bark obtained in past years by thinning and pruning. The experience gained on the plantation is sufficient to show that complete coppicing, *viz.*, cutting close to the ground all but a few trees, is a perfectly safe way in Sikkim of taking the bark crop. Trees from four to six years of age coppice better than older trees, but the method of partial coppicing results in failure with trees of every age.

THE Government Cinchona Plantations in the Madras Presidency yielded in 1877-78 138,838½ lbs. dry bark, which is a large harvest of bark than had up to that time been taken in any one year. It was thus distributed :—

		lbs.	
Crown Bark ...	Natural ...	32,857½	
	Mossed ...	24,679½	
	Renewed ...	12,003½	
	Branch ...	5,855½	
			75,395½
Red Bark ...	Natural ...	17,076	
	Mossed ...	25,392	
	Renewed ...	18,183	
			60,651
Other Kinds ...	Yellow ...	1,845½	
	Grey ...	677	
	Dust and Mossed...	239	
			2,761½
		Total ...	138,808½

Of this crop, 132,951½lbs. were sent to England, 1,000lbs. were supplied to the Government of Bombay, and 4,330lbs. to the Madras Medical Stores. It is observed that no record has been kept of the number of trees that were stripped and mossed, but that information on this point will in future be available. The trees on the plantations having now been numbered, and subdivisions formed, some sort of working plan can be probably framed, and the yield in each sub-division be estimated with fair accuracy. The harvest in the previous year was 103,341lbs. of which 102,384lbs. having been sent to England were sold within the official year now reported on for £30,434-12-0. The Commissioner takes no credit for any receipts within the year from the 1877-78 crop, but of the £33,231-12-10 which it fetched £19, 965-10-0 were realized before the 31st March last.

The prices fetched by the shipments of Crown bark during 1877-78 were still high, though below those obtained for the previous year's crop, *viz.* :—

	Highest prices. 1876-77. Crop.		1877-78. Crop.	
	s.	*d.*	*s.*	*d.*
Natural	13	9	8	4
Mossed	15	8	8	5
Renewed	13	5	11	10
Branch	15	7	10	6

Red bark, with the exception of "renewed" red, had much declined in value, *viz.* :—

	Highest prices. 1876-77.		1877-78.	
	s.	*d.*	*s.*	*d.*
Natural	11	0	1	9
Renewed	9	2	5	10
Mossed	4	7	2	8

In view of so large a harvest of bark, the plantations may be taken to be in a satisfactory condition; but the Commissioner states that there is still a difficulty in regard to labor, and that this led to "very little manuring," being carried out at Neddivattum and Pykara. It appears from the expenditure statements that only Rs. 461-4-9 were spent under this head against an estimate of Rs. 700, and that of this amount, Rs. 400-5-6 were expended at Dodabetta, while the Neddivattum plantations received 15-10-6, and those at Pykara only, Rs. 9-4-6. The favourable results obtained by manuring have been frequently demonstrated and led to the late Acting Commissioner making a larger provision on this account in the current year's budget. Every effort must be made to utilise this provision to the full extent, for it is above all things necessary that the trees should not be "starved" now that their recuperative powers are so largely taxed by the repeated removal of bark.

Scarcity of labour appears to have been also the cause of only Rs. 13,025-2-1, out of an allotted sum of Rs. 25,279, being spent on upkeep, and the subject demands serious consideration. It seems probable that the Government rate of wage is too low, and if found to be below that offered by private planters, it must be promptly raised. If this is done there should be no difficulty in obtaining coolies at Dodabetta, nor yet at Neddivattum, now that good lines have been built and arrangements made for storing grain against the monsoon. From the Commissioner's remarks in paragraph 6, there would appear to have been a tendency to subordinate the work of cultivation to that harvesting. This, the Government observe, must be checked, lest the future of the plantations be sacrificed to present gain.

The propagation of young plants appears to have been vigorously prosecuted, and the Government notice with satisfaction that 5,000 were planted out in the Dodabetta plantations. The public took 187,350 plants against 142,000 in 1876-77, whilst the demand for seed rose from 143 ounces to no less than 323lbs. Cuttings to the number of 170,500 were also sent out of the nurseries. The stimulus afforded to private enterprise by the success of the Government plantations could receive no stronger proof. Adverting to the Commissioner's remarks regarding the results of the small coppicing experiment of May 1871, the Government observe, that Captain Walker states in his report that suckers were left growing when the trees were cut, and that it is impossible now, to distinguish these from " real coppice shoots from the stool."

In September last, Mr. Barlow applied to Government for permission to propagate the rarer varieties of cinchona, such as *calisaya* and hybrids, for sale to the public, and incidentally alluded to by the Cinchona Committee being in favour of more extended propagation of all the varieties. The Government sanction operations, on a moderate scale, for raising every variety for which there is a demand. Some indecision has lately marked their action in this respect. A proposal by Mr. Webster for an enlargement of the nurseries, with a view to meet fully, if possible, all demands was negatived, as it involved an extension of the plantations, and it was considered advisable to encourage the raisings of seedlings by private persons, but it was not intended to put a stop to operations within the limits already fixed. It is now ordered that the attention of the Assistant Superintendent at Neddivattum should be mainly turned to the propagation of the calisaya species, as well as of any other variety that his experience may lead him to consider adapted to the circumstances of the Wynaad plantations ; but as long as a demand for *C. succirubra* and *C. officianalis* plant exists, these also should be reared as far as space will allow.

We learn that Mr. Woolley has concluded, through Messrs. Parry and Co., of Madras, the purchase of Colonel Fyers' Cinchona Garden on the Koondahs. This property was originally acquired by the late Mr. Schnarre, and is said now to contain some fine cinchona trees. The bark on the plantation was once removed, and the trees seemed to have renewed without the application of moss. Perhaps this was the work of shade. The fact is one deserving of notice.—*South of India Observer.*

CINCHONA AND HYBRIDIZATION.

(*From the Ceylon Observer.*)

DRS. HOOKER and Thompson, great and leading botanical authorities, represented hybridization or the crossing of species to be one of the rarest possible occurrences in nature. And the operation is often difficult and often baffled when all the resources of the gardener's art are applied. We were therefore, not a little surprised at the tone taken up by botanists in India and Ceylon about hybrization in the case of cinchonas. Planters were warned against it as the source of untold evil. While the late Mr. McIvor was experimenting in the production of hybrids, so as to secure improved plants, Mr. Broughton denounced the vegetable half-castes, as partaking only of the bad qualities of both parents! This in the face of the fact that the bark of a hybrid produced by Mr. McIvor was pronounced by Mr. Howard to be one of the richest he had ever met with. Mr. Howard wrote an able paper on the subject, and shewed how liable *C. officinalis* and *C. calisaya* were to sport,—a dozen varieties, or as Mr. Howard preferred to call them, *forms* being obtained from the seed of a tree apparently of pure type. Mr. Broughton wrote to Mr. Howard truly, that from the pure stock plants of *C. officinalis* he (Howard) had sent to the Nilgiris every possible form, large-leaved and small, sharp-leaved and broad, would be seen growing on Dodabetta. The changes produced in *C. calisaya* by the climates of the Nilgiris and British Sikkim were attributed to processes of hybridization for which really there had not been time. It will be in the recollection of our readers that the bark of true *C. officinalis* from Lool Condera, for which Messrs. Howard and Whiffen paid such high prices, was pronounced to be that of *C. calisaya*, or of a cross between that variable species and the true-to-type *C. succirubra*. It thus appeared that good results from crossing were anticipated. Our own sentiments have been often stated. We treat the idea of hybridization as a mere bugbear, while we believe in almost interminable variety or difference of form as the results of seed from the same plant. And even when cuttings are taken there are wonderful diversities of form. If the cinchonas we cultivate are hybrids, then the crossing must have taken place in South America. This is what botanist Kuntze says, according to a review we extract from the *Planters' Gazette*, and he goes so far as to characterize the famous *C. ledgeriana* as a hybrid. He also talks of it as sterile at the very moment that seed from trees the produce of Ledger's seed, is being received in Ceylon from Java Herr Kuntze not only believes in the hybridization of the cinchonas, but evidently does not believe in the goodness of any which are true to type ! So do botanists differ to the confusion of poor non-scientists like ourselves. What *are* we to think or believe? One thing we certainly take leave to doubt, and that is that that *C. ledgeriana* as a hybrid was accidentally produced in India.—What we do believe is that seed of *C. ledgeriana* produced plants differing widely, in accordance with climate, in Java, in Sikkim, and in Southern India. We prefer to hold with Howard to immense variety of form, rather than to constant tendency to "mingle, mingle." But, as Mr. Kuntze believes in endless hybridization, we wish he had revealed the secret of that *irregular* process by which barks with 12 per cent. of quinine are invariably obtained. Some of our friends who are so afraid of hybrid *C. officinalis*, will be horrified to see that Kuntze classes this kind not as a species, but altogether a hybrid! The review is as follows .—

THE CINCHONAS CULTIVATED IN ASIA.

Any contribution to previous knowledge of cinchonas and their most profitable culture is welcome. We are not in a position, however, to judge of the value of a great deal contained in the pamphlet quoted below ; but if Mr. Kuntze's claims to the honour which he covets rest upon the merits of this work alone, or even combined with his primeval freshwater ocean, his chances should be very slender indeed. Nevertheless, we give the substance of it for the benefit of our friends in India, who may be able to corroborate or controvert the writer's views. From the title we expected a monograph of the whole genus, but found it to include only the forms cultivated in Asia. In the course of his travels Mr. Kuntze visited the plantation in Java and in India, and he states that he is the first botanist who has comparatively investigated the Dutch and English plantations since they have been in a flourishing condition ; consequently he is in a position to publish many hitherto unknown facts. With regard to the yield of alkaloid, he says, " It is no small result of my cinchona studies that I can confidently propose a plan whereby in future it will be possible to obtain an average of 12 per cent. instead of the 1—4 per cent hitherto obtained." This is to be effected by planting hybrid forms, as the secretion of quinine is increased by hybridity. "And the more irregular the hybrid—that is to say the less the characteristics of the parents are blended in the offspring, the richer the bark is in quinine. At present only one irregular hybrid is known, *C. ledgeriana*, which yields from 5—13½ per cent. The latter equals 17·83 per cent. of sulphate of quinine, the maximum quantity hitherto found. Unfortunately this hybrid is mostly sterile, whilst all the other hybrids are extraordinarily fertile."

An "irregular" hybrid is the offspring of a species fertilised by the pollen of a hybrid, in which the characters of the parents, instead of commingling and forming an intermediate in leaves, flowers, &c., are separate and easily recognised. The present method of planting practised by the Dutch is in rows on gentle slopes in forest clearings at an elevation of 5,000 feet to 5,500 feet. Treated thus, Kuntze states they succeed well, and this mode of treatment he regards as better than that adopted by the English in India. All the kinds succeed in Java, whereas in most other plantations only *C. succirubra* succeeds.

According to the official report of July, 1876, there were then in Java 2,012,187 cinchona trees, namely :—

1,001,670	C. Calisaya—Hasskarliana
565,336	C. Officianalis
223,200	C. Calisaya—Ledgeriana
177,493	C. Succirubra and caloptera
44,030	C. Lancifolia
512	C. Micrantha

The Dutch are letting *C. succirubra* and *C. mircranthu* die out, because their bark is very poor in quinine ; whilst the English have planted little else than the former, the bark of which is unsuitable for commerce, as it usually contains only 1 per cent. of quinine against 3 per cent. of cinchonine. The number of cinchona trees in India is estimated at 10,000,000 to 12,000,000. With regard to species, Mr. Kuntze could only distinguish four in the plantations of Java and India, three of which he "was obliged to re-name; because the names by which they are known in cultivation are partly defective, partly connected with faulty descriptions, and partly include species and allied hybrids." This proceeding is all the more indefensible as the author recognises the fact that hybridity in the genus is illimittable. His species he places in two groups, characterised as follows :—

A. Leaves small, dark green, ribbed almost coriaceous leaves, regular capsules, and funnel shaped fruit calyx.

1. C. Weddelliana, Kuntze ; C. Calisaya *pro parte.*
2. C. Pahudiana, Howard.

B. Leaves ample, light green ; thin capsule ventricose, beaked.

3. C. Howardiana, Kuntze ; C. succirubra, *pro parte.*
4. C. Pavoniana, Kuntze ; C. micrantha, *pro parte.*

C. lancifolia mutis, C. officinalis, L., C. scrobiculata, Hb. et Bpl., C. Purpurea, R. et P., and several others are regarded as hybrids of American birth. The *specierum hybridar umque clavis* is no doubt carefully elaborated, as the author has had some practice in "re-forming" the classification of Brambles ; but we fail to see the utility of it. In the first place it is admitted that the species freely hybridise, and the hybrids cross with each other and the species in the most indefinite manner. Secondly, will any one planter label a certain hybrid according to its pedigree as follows : "*C. Howardiani-Pahudiani cum Pahudiana denuo cum Pahudiana Weddelliana*"? Each succeeding generation of seedlings, if the off-spring of cross-fertilisation, which they most likely would be, would get an additional name. The hybrid C. Ledgeriana was orginally brought from America by Mr. Ledger, who found it 120 *leguas* from Pelechuco in Bolivia, and it has also been accidentally raised in India ; Kuntze recognises it as the offspring of the hybrid Pavoniani-Weddelliana fertilized with pollen from one of the original parents, and as it is sterile he proposes raising it artificially in the manner indicated. Respecting C. micrantha, the author says that the larger the blade of the leaf is, the shorter is the petiole ; but this is not in accordance with our experience.

CONTENTS:

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah *in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.*

LETTERS TO THE EDITOR.

CHEAP PLOUGHS.

SIR,—I learn from the Report of the Agri-Horticultural Society published in the *Agriculturist* of January, that wooden ploughs on the American pattern "can be made here (Calcutta) at from Rs. 12 to Rs. 15, whilst light English ploughs for a single horse or pony, cost from Rs. 45 to Rs. 50." Would you let me know whether Dr. S. Lynch could supply ploughs on the American pattern at Rs. 15? An authoritative reply would oblige your correspondent as well as several others in this district.

S. DATTA.

Bishwanath, Assam.

EUCALYPTI.

SIR,—I see a correspondent enquires whether Eucalypti have been known as yet to bear fertile fruit in India.

I presume the Eucalypti in the Neilgherries have been bearing seed for many years. As regards the Punjab, I can state that a tree planted by Mr. Perkins, C.S., in the garden of the Deputy Commissioner's house at Hoshiarpur, about 12 years ago, and now about 50 or 60 feet high, bears a small quantity of fertile seed. Also, that the Eucalypti planted at Abbottabad in Hazara district seeds freely, for I have had several pounds of seed sent me from that station. The growth of the Eucalyptus in Hazara is very rapid: and it is probably there that its greatest success in the Punjab has been attained.

The species are so difficult that I cannot be sure of the species either by the tree first mentioned, (there are now many of the same kind in the station and district of Hoshiarpur) or of the Hazara one. I think however the species in both cases is identical. It is *not Globulus. Globulus* does not readily succeed here. It is not *Rostrata*, which is easily identified by its long thin leaf, and willow-like stem in the young plant.

Hoshiarpur, 16th January, 1879.

EXPERIMENTS IN WET CULTIVATION.

SIR,—I have much pleasure in enclosing for your information and that of the subscribers to the *Indian Agriculturist*, a detailed statement of the results derived from deep ploughing on paddy lands, carried out during the years 1875-76 and 1877 by an enlightened native resident in the French settlement of Karikal in this district.

To ascertain the yield per acre deduced by these experiments, I would premise that the *veli* of land measures 6·6 acres, and inasmuch as 20 *mahs* go to one *veli*, one *mah* is as nearly as possible one-third of an acre.

The yield of paddy therefore per acre, it will be seen, was nearly 82 *kalams*. A *kalam* is equal to 24 Madras measures of paddy, or 12 Madras measures of rice weighing in the aggregate, say, 36lbs. So that the yield per acre amounted to 82×36lbs., or the respectable quantity of 2,956lbs., or nearly 30 bushels (taking *wheat* as the standard).

The ratio of yield on lands treated scientifically and non-scientifically is, it will be seen, as 5·4 to 1 in this instance of wet cultivation.

R. R. E. BROCKMAN,
Captain R. E.

Tanjore,
21st, December 1878.

IN Soopprayapooram, a village attached to Maganum of Tironnellacr, 3 miles from Karrical, I made the following experiments, induced to do so by the study of Mr. Robertson's reports.

Plot No. I.—It contains 230 gulies (2 mahs and 30 gulies) and is a sandy soil. During dry season no cracks are apparent on the surface.

Plot No. II.—Sandy on the surface, and no cracks during dry season; but the sub-soil is quite clayey. They call it *Ooki kilar*. Even during dry season, when the surface is firm, there were unsound clay places below in which cattle would sink to the knee. These they always avoided and would pass only when forced. It contains 580 gulies (5 mahs and 80 gulies).

Plot No. III.—Stiff clayey during dry season full of deep cracks containing a little more than 200 gulies or 2 mahs. When blocks of this stiff clay were turned, they contained plastic clay containing moisture, whereas on the surface and bottom it was dry earth.

In 1875 I bought an English plough called Howard's Combined Plough, and as it was in pieces nobody at Negapatam knew how to fit it together (though we could form some idea of it from seeing a figure of it in the Agricultural Class Book) till a Brother of the Society of Jesus, in St. Joseph's College set it all right very soon. I must say that this was one of the ploughs supplied by the Madras Government some years back and three Mirasdars bought it to please the taluq authorities, and it was never used by them, and was lying idle at Negapatam, where I managed to get it.

Soon after harvest in the middle of February 1875, and before the commencement of the dry season, the 3 plots were ploughed up to the depth of 6 inches by the said combined plough. Buffaloe bulls such as are used in drawing carts were yoked, and pulled the plough with ease. All the 3 plots were ploughed twice.

In plot No. I, twenty five cart-loads of ashes and street sweepings were applied towards the close of May or the beginning of June.

In plot No. II., twenty carts of the said manure and 40 carts of tank scourings (at 8 cart-loads for a rupee) were applied.

Plot No. III had no manure.

Plots Nos. I and II were grown with Arupatham Kuruvay paddy, and plot No. III with Segappu Sermmany paddy well suited for seasons of drought. Though the former paddy is called Arupatham Kuruvay (60 days Kuruvay) it actually takes almost 3 months for harvesting. It was sown in the month of June which is generally the commencement of cultivation season in that part of the country. As soon as water was let in, country ploughs were used for puddling, and within 3 days the plants were transplanted. The Kuruvay seedlings were from 18 to 22 days old. The Kuruvay plants were watered as country paddy plants.

Plot No. I gave (33) thirty-three kalams, of Kuruvay paddy and plot No. II gave (48) forty-eight kalams for the first crop. After Kuruvay harvest I applied 2 cart loads of Kivaley po udu in plot No. 1 only. This plant is used as manure in many villages about Karikal and grows in sandy soils near the coasts. I don't know if it is the wild indigo referred to by Mr. Robertson, I have not seen this plant in the interior. After cultivating with country ploughs I again raised Chumba paddy in plots Nos. I and II.

Plot No. I gave me (30) thirty kalams, and plot No. II gave (35) thirty-five kalams, and plot No. III gave (18) eighteen kalams and only one crop was raised on it.

Next year, which was one of general drought, plot No. 1 alone was grown with double crops as before. This year plot No. I had not a[illegible] manure. About only 5 carts of cowdung were applied and about 50 sheep were folded in the said plot for about 20 days, whose manure was ploughed in. The said plot No. I [illegible] double crops of Kuruvay and Chumba paddy, gave (60) sixty kalams. Plot No. II had no double crop as about the time of transplanting Kuruvay seedlings the irrigating channel was dry. Of course plot No. III had never double crops and it yielded very much the same as before [illegible], 18 kalams. This plot was too low and generally inundated. It is also situated amidst the fields of Kallundai paddy, which is suited for lands of low level and the plot was not manured. In this year (say) only which was one of general drought, the effect of deep ploughing was very striking.

For when the adjoining fields had suffered from Suley or Kulichombu my cultivation did not suffer. The deep ploughed soils retained moisture till water came in, while other lands not so ploughed, suffered.

In the 3rd year the same thing was done as in the year preceding and plot No. 1 of 2 mahs and 30 gulies never yielded less than 60 kalams for two crops and ranged from 60 to [illegible] kalams after paying the charges of reaping and threshing when as before the experiment the said plot scarcely yielded 10 kalams. The result of the other plots are also satisfactory in that, while the average produce of these plots as well as of similar plots in the village under the ordinary system, was about 100 kalams a veli, or 5 kalams; [illegible] the produce under this experimental system was more than [illegible] that quantity. I am sorry the exact quantity of produce under the old system for the same plots was not recorded before.

The inferences to be drawn from this are—

(1) The excellence of deep ploughing cannot be doubted for one moment. The mere driving through the soil is incomplete, and it must be turned by deep ploughing.

(2) That ploughing when the soil is dry soon after harvest, is conducive to its enrichment, as it lets the air, light and rain reach the soil.

(3) That plants in deep ploughed lands withstand drought better than in surface cultivated soils, and that plants in the former are free from diseases which attack the latter during drought.

(4) That at the rate of yield of plot No. I containing 2 mahs and 80 gulies (which ranged from 60 to 63 kalams for 2 crops) 1 veli of land can be rendered fit to yield more than 510 kalams when scarcely 100 kalams a veli is the average of the produce of similar lands in the said village.

P. SAVARAYA PILLAY.

WELL IRRIGATION.

SIR,—I see by your columns that a scheme for well irrigation is on the *tapis*. Of course if the Government undertake it, well and good; if not, I think it would be a good change for capitalists or a Joint Stock Co., to make wells, renting them to cultivators at a reasonable percentage on outlay. I have always advocated the multiplication of wells for irrigation purposes. A well will irrigate about 10 acres, and would be a great means of preventing, famines in the event of drought—in fact, if the Persian wheel was introduced into the N.-W. P. and Bengal, it would be a great improvement on the present means of irrigation by "dhoakis" or water-lifts used by natives. The cultivators themselves have not the means of making wells generally, but would not be glad to rent them. In fact the introduction of Artesian Wells would be a great advantage. I believe it has been used with great success by a gentleman in Madras, the cost being less than that of a well. India wants irrigation, and the introduction of a better kind of plough. I believe some experiments have been made at the Calcutta Jail with great success with a light American plough, costing about Rs 15. Its introduction would be an advantage, as by the wretched ploughs now in use by the natives, the soil has to be ploughed up 5 and 6 times before it is fit for sowing. The labors of the Famine Commission it is hoped, will develope a better system of irrigation and improved methods of working the land; but that great incubus, the money-lender, must be brought within bounds, as otherwise little improvement in the social condition of the cultivator can be hoped for.

PHILO.

Calcutta, January 8th, 1879.

GIRDLING APPLE TREES.

SIR,—The girdling of apple trees, is a practice which, though not generally known in England, has been adopted by many gardeners to improve and increase the yield of fruit. The process is a simple one and is carried out I believe, by stripping the bark off the lower branches or the main stem of the tree when the flower blossoms. I would like to know whether girdling has been tried in India, and if so, with what results.

The cultivation of the apple is carried on to a large extent in Bangalore from which place the fruit is sent to many parts of India. But it has only been within the past decade, that anything like scientific training has been brought into operation through the exertions of a few gentlemen here. Added to this a very large variety of the apple fruit has been imported from year to year, which having now been acclimatised grow in great luxuriance.

It would be interesting therefore to know what further improvements in *grafting* and *cultivating* could be introduced, and I should be glad if any of your numerous readers could give me hints or information through your columns on the subject matter of this letter.

THOS. J. LEONARD.

Bangalore, 2nd December 1878.

FERN CULTURE.

SIR,—*Cycadaceæ* require a rich sandy loam and moist heat, propagated by means of suckers. There are two species cultivated in Calcutta.

C. circinalis (round leaved), 3 feet high, found in India about 1800, yields a coarse sort of sago.

C. revoluta (rolled-back leaved), 3 feet high, found in China in 1737.

Zamia.—Soil as above, but require to be imported, as they do not propagate in India. They are indigenous in the Bahama Islands, Cape of Good Hope, New South Wales, and West Indies: In the latter

country arrowroot, of the finest quality, is made from *B. furfuracea*. In the Botanical Gardens, Calcutta, there are two or three species.

G. P. P.

THE SAME.

SIR,—Your correspondent Dr. Shortt, states that the seeds or nuts of the cycads "are eaten by the poor ground into a flour and cooked into a sort of a conjee." Now I would not advise any of your readers or your correspondent making a trial of it. Unless prepared as I shall describe, it has poisonous properties, and sometimes proves fatal, but generally causes severe vomiting, the only antidote for which is large doses of tamarind water, until the vomiting ceases. The plant is quite common all along the Western Ghats, in Travancore and Malabar, but is not found at any great height on the Hills. It often has two or three heads or branches. It seeds during the S.-W. monsoon, and sheds all its leaves in December or January, which its puts forth again after the first shower of rain, after the hot weather fires have burnt the forests The trunk of the plant contains a very large percentage of coarse fibre (I should say 74 per cent) which should make a good "half stock" for paper manufacture, and as good as that produced from bamboo. A transparent glutinous fluid like the white of an egg exudes from the tree when cut, and forms into a gum. The average from a tree will be about a quart; its properties are not yet discovered. The Kordars and Mulcers of the Anamalais live on the nuts for some months It is prepared in the following manner before being used as food. As soon as the nuts are ripe, which is when they assume an orange red or yellow colour, they are gathered and taken to a flat rock and cut open, in two, the kernels are taken out, sliced and dried out in the sun for three or four days, until the thumb-nail makes no impression on them by pinching; they are then gathered and soaked in a stream of running water for three full days, after which time they are dried and stored for use. The kernels are eaten roasted, or made into flour for conjee, or sweet cakes with the addition of honey. It contains, I think, a good quantity of starch, the taste after being prepared is not at all disagreeable. It is not eaten largely in Malabar or Travancore, but on the Anamalais, the nuts are not even allowed to become properly ripe before they are removed by the Hill men While on the subject of the above source of food of the wild tribes, I may as well mention another food supply of the Mulcers, and that is the ripe pulp of the tamarind which is quite common about the valleys of the Anamalais, they live on it for a month or two. I once had the opportunity of witnessing this strange banquet. A group of about a dozen half-naked, dirty men women, and children, were squatted around a fire made of a particular kind of wood (*Anogeissus latifolia*) and a heap of tamarind with the shell Each one took a piece removed the shell, rolled the pulp well into the ashes and then lifting up their woolly heads, and opening their hy ena like mouths, the fruit was put down their throats and swallowed, seeds, and all, each man and woman consuming three or four lbs at each meal. The object of the ashes was to remove the acidity of the fruit, and to prevent it acting on the bowels.

BIG BORE.

BAMBOO AS PAPER STOCK.

SIR,—Bamboo is largely used in China for paper manufacture. It is cut while still green, scraped, and cleaned, the fine shavings are steeped in water and reduced to a paste by a particular method, mixed with isinglass. This paste is converted into various kinds of paper Before being bleached the paper is smooth, soft, of great strength, the colour being light yellow. The coarse shavings are also made into thick sheets with which a very useful tinder is manufactured. The tinder is made with rolls of paper which are lighted, and when thoroughly ignited are thrust into small tubes of bamboo which are at once closed and the flame thus put out: the burnt roll can then be kindled with a flint and steel as required, blowing on it a few times lights it into a flame, being the only kind of tinder that possesses this peculiarity. Mixed with slaked lime the paste is made into a strong, useful and ornamental plaster for walls of buildings. The thicker shavings can also be used for stuffing cushions, pillows, &c.

I.

COFFEE LAND TAX IN MYSORE.

SIR,—Why have you not ere this published the Minute on taxing coffee lands in Mysore in your valuable paper? Mr Gordon, C. S. I., Chief Commissioner of Mysore, has published a Minute on coffee and sent the same to the Governor General for sanction.

Should the Government of India sanction what Mr. Gordon has asked them to do, it will ruin nine-tenths of the native coffee planters in Mysore. I will not take up much of your valuable space Mr. Editor but will show you how it will affect the natives. At present the natives as well as the Europeans pay an export tax of one rupee a cwt, or at any rate they are supposed to do so, but the native does not export his coffee; he sells it on the spot or at the nearest market town in his talook, so the merchant who purchases, and not the grower, pays the duty. Mr. Gordon proposes to levy a tax of one rupee eight annas an acre instead of export duty. The opinion of the Mysore Planters' Association has been asked for, and the reply is that one rupee an acre is as much as coffee land in Mysore can stand; the opinion of individual European planters has been asked for and replies from *five* of them have been received by Government; but Mr Gordon forgot to ask the opinion of a single native planter I have pointed out to you that the native does not pay anything just now, but the export duty is paid by the merchant Under Mr. Gordon's new scheme the native will have to pay the tax whether his lands produce any coffee or not. No warning has been given to the native that a tax will at any time be substituted for, and instead of the export duty, neither has his opinion been asked whether he would consent to the tax or not.

From and after the 1st of April 1879, the tax must be paid or rather ought to be paid, but 95 out of 100 of the natives will give up their holdings. They cannot afford at present to pay the tax proposed; they have had no warning, hundreds of them in fact will not know that a tax on their land has to be paid until they are called upon to pay down one rupee eight annas per acre for every acre they hold.

The Chief Commissioner's Minute on coffee is well written, but very misleading to the Government of India as far as the natives are concerned, and if it is true that the Chief Commissioner wishes to drive the native planter from his holding he will succeed without a doubt. I trust the Government will withhold its sanction to this paper until they are in possession of more information as to how the tax will affect natives. Give them a warning that after a time say three years, the tax will take effect, and then if they cannot afford to pay, it will be their own fault, but without any warning, to allow the natives to cultivate and make their places produce at least six maunds an acre, I think is most unfair. I have heard it whispered that Mr. Gordon wishes to drive the natives out of the way as far as coffee is concerned to allow of more Europeans coming into *Mysore*. I am as I have said above, certain that should this proposal of Mr. Gordon's become law, the natives must go to the wall, but I have my doubts as far as the Europeans are concerned

MORE ANON.

Kadur District Mysore, 22nd December, 1878

MUMMY PEAS.

SIR,—With reference to recent correspondence I may mention that when I was staying in the Isle of Man about the year 1852, my host obtained some mummy peas which germinated. The plants grown were trained against a wall and reached some 10 feet in height. They resembled the ordinary pea in every respect, except size. The pod was as long as a man's hand and contained 15 or more peas about the same size as what are known as marrow fats. I left the Island afterwards and can give no account of the subsequent experiments. My impression at the time was that the peas were the product of "repeated selection of the fittest" It would be interesting to know if such deteriorated afterwards to the original size.

C.S.

P S—If I remember rightly the peas were obtained from a mummy in the Exhibition of 1851.

KANS GRASS MR. SCHROTTKY'S REPORT.*

(*To the Editor of the Pioneer.*)

SIR,—Your reference, in a recent issue, to my report on kans grass, published lately in the *N.-W. P. Gazette*, with Mr. Cadell, the Banda Settlement Officer's review thereon, has recalled the subject to my mind and I hasten to correct a most serious error and an oversight of an important portion of my report, which underlies both yours and Mr Cadell's review. *It is precisely the error I foresaw, and which I* endeavoured to prevent by dwelling at some length, in my report, on the nature and the difference between *available* and *unavailable* plant food, which otherwise would have been quite out of place. I stated that on the basis of my experiments, and analysis of the different soils submitted to me, I have come to the conclusion that "an over-saturation of the soil with *available* lime and silica and *notably the latter*, is essential and necessary for the germination and development of kans." I would draw your attention to the words italicized. Mr. Cadell referring to the fact that some soils, also overrun with kans, are shown, by the results of ordinary chemical analysis, to contain much less lime than other soils which are never affected with kans, thinks that my conclusion that an over-saturation of the soil with available lime is

* See pages 53-56.

necessary for the development of kans, will probably require some modification. Probably it will, as it appears that the soils sent to me were by no means fair representatives of the chief classes of soils in which kans is found to be prevalent, but Mr. Cadell has overlooked the fact that I said *available* lime, the word *available* deriving special significance by my preceding remarks explaining the nature of a difference between *available* and *unavailable* plant food. Referring to my analyses of the soils, you will observe that ordinary chemical analysis shows the percentage of total lime in the three different soils.

	No. I. Kans.	No. II. Kans.	No. III. Kans.	Proportion.
Total Lime	6·50	10·60	9·09 per cent.	1 to 1·63 to 1·55

The available lime which may be considered as fairly represented by the average of what can be extracted from the soil by percolation with weak acids and water, stands in the following proportions.

In 1000 grs. of soil, extracted by weak acids.

	No. I.	No. II.	No. III.	Proportion.
Available lime	12·2,	30·3,	28·5 grs.	1 to 2·48 to 2·33

In 10,000 grs. of soil, extracted by distilled water.

Available lime	0·6,	10·3,	11·2 grs.	1 to 17·66 to 18·66

Average proportion of available lime in soil free from kans to that in soil overrun with kans 1 to 10·07 to 10·49

The proportion of *available* lime in the different soils varies therefore immensely from the proportion of the total quantity of lime, as shown by ordinary chemical analysis, and as only that proportion of lime which exists in the soil in the *available* state, can influence plant life, any conclusions based upon the relative quantities of available plant food which are found in soils, cannot be modified, or affected by the results of ordinary chemical analysis which gives available and unavailable plant food under one heading. As a matter of fact, ordinary chemical analysis may show two soils to contain say No. I., 5 per cent., No. II., 10 per cent. of lime, while the proportion of *available* lime in them may be the very reverse, *i.e.*, No. I. may contain 1 per cent, No. II., ½ per cent. Until therefore we know the proportion of *available* lime in *kabar* and *parua* soils, overgrown with kans, and its, proportion in the *same class* of soils, free from kans, we must still consider the question an open one. I wonder Mr. Cadell was not struck by the apparent incongruity of my recommending heavy dosing with lime as a remedy against kans, which I say is due to an excess of it in the soil. Add, however, the word *available*, with all the weight it carries in my report, and the apparent absurdity ceases to exist.

It does not matter how much lime there is in the soil, provided that there is no excess of it in that peculiar state of physical combination with the soil, in which alone it can influence plant life. But though from the results of my experiments and analyses, I was bound to consider over-saturation with available lime as an *accessary* in encouraging the germination and development of kans, and though Mr. Cadell has done well to draw attention to the fact that kans is likewise prevalent in soils, shown by ordinary chemical analysis to be less rich in lime, he has not, I think, drawn sufficient attention to the prominence I gave to available silica, as the *chief* cause of the spread of this pernicious weed. I said: "An over-saturation of the soil with available lime and silica, *and notably the latter*, is essential and necessary for the germination and development of kans."

EUGENE C. SCHROTTKY.

Calcutta, 28th December 1878.

HILL FARMING.

SIR,—*The Indian Agriculturist* couples my name with an enquiry, as to whether the public could not obtain some information as to the working of the Lawrence Asylum Farm, and enquires whether a statistical report could not be made, showing what the results are likely to be:

I believe a statistical report is annexed to the usual Annual Report of the Asylum, but as this report has but a very limited circulation, the public does no benefit much by the information given, and as I think the subject of Hill farming deserves a great deal more attention than it has received, I venture to offer the *Agriculturist* the benefit of my experience.

The question asked by the *Agriculturist* is "what may be expected of it?"—whether the Lawrence Asylum Farm, or farming in general is meant, I do not quite understand.

With regard to the L. A. Farm in particular, I have some doubt as to its success; it has a good deal to contend with. In the management of a farm, freedom of action is of the first importance, and this the Manager of a Government or semi-Government establishment cannot expect to have; the directing powers must and will have their say and way, whether they understand the matter or not, and the consequence is obstruction, and annoyance, and discouragement to those who are entrusted to carry out designs.

There is another matter that tells heavily on affairs of this kind, that are carried on by Government—*perquisites*. It seems to be a thing pretty generally understood that a man's Government pay should be augmented by perks, whenever an opportunity offers, and the farm authorities, in taking advantage of their chances, only follow a general rule. The perks from a farm are of course free table from farm supplies. I think I may, at a low estimate, put the loss down under this head at Rs. 2,000 per annum cash, and taking into account the demoralizing effect that such a system has, I think there is little chance of a Government Industrial Establishment being successful, in a pecuniary point of view.

I do not say the system of perks is wrong, I suppose it is a relic of the good old times; but I call attention to it, to show that supposing the L. A. Farm to turn out a failure, it is an item that should be taken into account.

The success, or non-success of the farm is of little direct importance to the public: what is required to be demonstrated is whether farming on the Hills is or is not likely to pay as a commercial speculation; and on this point I have very strong opinions; I say most unreservedly that it would. Always of course given that it was carried on under good management, the reasons I have for believing so are the following.

Compared with England.

1. Rent is much lower.
2. Taxes are almost *nil*.
3. The climate is better.
4. Growth is more rapid.
5. There are large areas of free pasture.
6. There is a greater length of growing season.
7. There is less competition.
8. There is, and always will be, an almost unlimited demand.

I know some of these statements will be disputed, particularly the last. I was often told when opening the farm, that it was no use to grow good things, that no one would buy them. I was also told (a thing that an Englishman ought to be ashamed to speak) that I should be beaten out of the market by native competitors, I prophesied differently, and experiences proved that I was right. The greatest difficulty the farm had to contend with was to meet demands. There seemed no limit to the business that could have been done, and this can easily be understood. Any one who has resided on the plains, knows how jaded the appetite becomes, and how eagerly it welcomes anything in the shape of change, especially anything in the shape of fresh vegetables or salad, and for the production of these things the climate and soil of the Hills are singularly suitable. The Neilgherries should be veritably the garden of Southern India and if a regular supply was organised, the consumption would be enormous, as they can be carried very long distances. I have sent supplies as far as Secundrabad, and they were reported as arriving fresh and good, and I have myself eaten vegetables, a week after their arrival in Madras, and when brought to table, they were in prime condition.

But it is not as a vegetable-producing district that we should look for prosperity, this at the best would be a limited branch of industry. What should be aimed at, is the production of meat, instead of the inhabitants of the Hills being dependent on the plains for supplying them with a lot of wretched, bare-boned, goat-haired abominations, in iscalled sheep, and good-for-nothing half-starved cattle, from whose bones it is difficult to pick a meal; we ought to be sending large supplies of well-fed meat to the plains.

I now proceed to show what I consider to be the capabilities of the Hills as a meat producing district.

The first and most important consideration is what description of stock is most suitable, and I have no hesitation in saying that sheep stand first. It seems to be believed that the Hills are unsuitable for sheep, on account of the heavy and continuous rainfall during the monsoons, but this argument is put forward, either without thought, or without knowledge of the condition under which the animal thrives. There is scarcely an animal so well protected against rainfall as the sheep; it's thick and only fleece is as nearly waterproof as the feathers of a duck, and it seems to have been a special provision for the protection of the animal from wet and cold. It will be said experience proves that excessive rainfall in England is highly injurious to sheep. True, but the circumstances are widely different. Heavy rain in England means poached and sodden land, and as sheep are generally folded, night as well as day, it follows that during these times they have no dry place to lie on, and this is certainly injurious; but here this would never occur; in the first place the land never becomes soddened, even during the heaviest rains, and half-an-hour after rain has ceased to fall, the pastures are perfecty drained. Secondly, it is compulsory to house sheep here as a protection from wild animals, and this, with ordinary care in the construction of buildings, would ensure their having dry and comfortable sleeping places. It is of importance

to remember that it is not the actual rainfall from which sheep suffer, but from the want of drainage. Some of the most unhealthy sheep farms in England have been converted into sweet and healthy pastures, by simply draining. The chief diseases from which sheep suffer in England are catarrh, and foot and belly rot. The first is doubtless caused by exposure, and lying on wet ground; the second from want of dry footing, and the last from feeding on sour, and badly drained pastures. They need not be exposed to any of these causes here, the undrained portion of hill land does not extend beyond the few swamps, scattered here and there, and no sane person would graze sheep on a swamp.

Again, it appears to me that Hills are the natural habitat of the sheep. I have never heard or read of them being found in their wild state in a low flat country. All the sheep and goat tribe are found on mountain ranges. It is also known that the meat from the sheep fed on mountains is superior in flavour to that fed on plains. These things show clearly that Hills are their natural home, and why should the Neilgherries be an exception? I maintain they are not. On the contrary that they are singularly suitable. As a rule Hilly districts are unsuitable for cultivation from the thinness of the surface soil, but here we have thousands of acres capable of being brought into the highest state of cultivation, and specially adapted for the growth of the turnip, the very thing on which successful sheep-feeding depends; and another thing of great importance in feeding—oilcake—is within easy reach. On the whole, I can hardly conceive a more favorable locality for the industry; here are the prospects; a delightful climate, immense areas of free pasture, a splendid turnip growing soil; Oilcake close at hand, and an unlimited demand for well-fed meat. These are the theories, now let us come to the facts. The L. A. Farm has a flock of sheep, the original flock of which was purchased locally, in common with all other animals on the Hills; they are of no distinct breed; they are brown faced, short woollen animals of pretty compact forms, and weighing, when fatted, about 12lbs. a quarter. They yield mutton as sweet as the celebrated Welsh meat so much prized at home. I take them to be about the stamp of animal suited to the Hills. The large heavy lowland sheep would be quite a mistake. To bring such animals here would be acting contrary to nature, small, lightmade animals are the things for Hill Ranges, all over the world. These sheep from their first arrival at the Farm, were very unfavourably situated; then sheds, not having been built for the purpose, had no drainage whatever, and the Farm, being always overstocked, it was impossible to make any provision to help them over the scarce season. So that in the dry season they suffered from a scarcity of food, and in the wet from a wet sleeping place, and still they throve fairly well. They never suffered from any epidemic disease. Not a single case of foot, belly rot or of fleece maggots occurred during the time I had charge of them, some three years. There was considerable mortality among the lambs, but nearly all this could have been prevented by good housing and suitable pasturage for the ewes.

So far theory and practice agree, we now come to the highly important matter. Supposing the foregoing to be correct, would it pay to breed them? This is the all important question, and here is what I know about the matter. I put up some wethers to feed, at 2½ years old; they were bred upon the estate, and up to the date of their being put up to feed, they had cost *absolutely nothing*. They had grazed their living from the time they were lambed; and the last of their herding and housing was amply repaid by the manure deposited during the nights. They were fed as follows:—a dozen were selected from the flock, and were driven out easy distances to pasture (uncultivated) up to about 1 P.M., previously having had a small feed of oilcake and turnips. During the afternoon they were again fed on oilcake and turnips; their allowance was 1 lb. of cake per diem, and turnips *ad libitum*, the latter was not weighed to them, but I should suppose they consumed about 8lbs per diem. Considering that two rupees per ton was the calculated cost of turnips, the latter item was not of much consequence. After six weeks feeding, six of the animals were brought to the knife, in prime condition, and they averaged about 40lbs each. The meat was bought readily at 6 annas per lb. We have thus:—

Cost of feeding per sheep 336lbs of turnips, about	...	0	5	0
...lbs. of cake	...	2	0	0
Rs.	...	2	5	0

PRODUCE.

40 lb. of mutton at 6 annas ... ... Rs.	...	15	0	0

The skin and offal are calculated to pay for killing, and distribution of meat.

I could go on much further on the subject, but I should think what I have said is enough to call attention to the matter. I will, before I conclude, call attention to the value of sheep as manure collectors, with a few women or children to collect ferns or other bedding, it is astonishing what a large quantity of rich manure a flock of sheep will give. Another important matter is that there is no necessity for being confined to a breeding season, the flock will breed all the year round. Many of the ewes at the Farm had three lambs in a year; two at one birth, and one at another. Keep them well fed, and there is no fear of deterioration from too frequent breeding.

J. BARNARD,
Late Bailiff, L. A. Farm.

AGRICULTURAL SCHOOLS FOR BENGAL.

To

A. W. CROFT, ESQ., M. A., DIRECTOR OF PUBLIC INSTRUCTION.

SIR,—With reference to the letter dated the 12th August 1878, I have the honor to submit the following sketch of a plan for imparting agricultural education in this country.

From time immemorial agriculture has been carried on in this country without the aid of any book or school instruction. The knowledge of the simple method which the farmers adopt for cultivation is acquired by tradition and observation of the practice of others.

The plan which I propose is to replace tradition and individual observation by school teaching, and to extend the scope of the teaching to the improved method of cultivation deducible from the application of science to agriculture. For this purpose I propose to establish classes in existing schools where instruction may be imparted on the following subjects: *viz*:—1st Elements of Botany; 2nd—Agricultural Chemistry; 3rd—The influence of climate on Agriculture; 4th—The character of soils and their relations to plants; 5th—The influence of seasons on Agriculture; 6th—Acclimatization on the introduction of foreign plants, and the conditions necessary for success in such operations; 7th—The invigoration and exhaustion of land, including ploughing, the employment of manures, the rotation of crops, and the influence of leaving lands fallow after cultivation; 8th—The employment of hitherto unused vegetable products to purposes of art and manufacture.

The first named subject must form the ground-work of all subsequent teaching and especial attention should be paid to it. At present, Botany forms a subject of study in many schools, but there is no fit book nor any teacher for it. The work required for Botanical instruction in this country should be practically treated, and illustrated with examples from native plants. It should also be so framed as to contain ample instruction bearing directly upon agriculture.

For the second subject there is also no work now available but the desideratum should be easily supplied.

Under the 3rd and subsequent heads, my work entitled the *Krishi Durpan* is the only one now available. It contains much information which if brought to the notice of agriculturists would be of great use, but it would be necessary to revise and extend it considerably for use in a college.

At the first start I would not suggest any thing that would involve heavy expenditure, my wish is to begin from a nucleus to be extended from time to time as it may prove successful. The first requirement is a complete staff of teachers, and, until this is produced, no school can be established with any prospect of success. To supply this desideratum, I propose first, to open an agricultural class in the Normal schools of Calcutta, Hooghly, Dacca, and Midnapore. Four teachers will be required for the purpose, and these I believe are available. It will be their duty to teach the subjects above enumerated, and at the same time to compile text-books.

At the beginning it will be necessary to offer special encouragement to the pupil-teachers who will attend this class, and I propose the increase of their stipend by four rupees monthly.

To control the action of the four teachers, and to give uniformity to the course of education proposed, it will be necessary to appoint a superintendent; who should attend each Normal school for two months every year, to deliver lectures and to manage the farm that should be attached to each school for the practical instruction of the students. The remainder of his time should be devoted to travelling in the country for collecting seeds and plants, which may be either introduced to the farm, or preserved for making a herbarium in each school for the Botanical study of the students.

When the supply of teachers available from the Normal schools shall warrant the measure, I would propose to open agricultural classes in zillah schools, grant-in-aid schools and village-schools, where the boys have passed the 16th year of their age.

As there are two classes of men in each profession, a managing class and a working-class, so in agricultural education it would be so arranged

as to produce in the higher schools a body of scientific agriculturists from the higher order of society, and in the lower schools it will be taught to cultivators, who will be thoroughly proficient in practical work.

To the former it may be at first desirable to give some encouragement such as remission of the school-fees. I am sure the poor boys will readily apply for their admittance to the agricultural class, and if they be allowed a share of the farm produce they will look upon it as ample.

In the zillah school of Baraset an agricultural class was once opened for the education of the boys in agriculture, but, for want of a teacher, this class had to be abolished. If the same class be again opened and all the lands formerly occupied by the model farm be granted for experimental purposes it should readily be revived.

In connection with the agricultural class in each school it will be, necessary to lay out a farm of not less than a hundred biggahs of land, for the practical instruction of the boys in a small part of it. Experiments of various kinds should be instituted, for improvement in the methods of cultivation and acclimatization; and, in the rest, indigenous cultivation should be carried on, for realizing a certain sum which may supply all the expenses of the farm and the cost of labour. As there is no means to keep a farm attached to the Calcutta Normal school, it is desirable that the students should attend the Imperial Botanical Garden for the practical study of botany and gardening. Their travelling expenses to the garden will amount to about Rs. 15 monthly.

Each farm will have to be supplied with the necessary implements including two ploughs and four bullocks.

A small laboratory and a monthly allowance for chemicals will have to be supplied to each Normal school. The total cost for these is not likely to be heavy.

HURRY MOHUN MOOKERJEE.

Calcutta :
Normal School, 21st October, 1878.

A NEW SOURCE OF REVENUE FOR INDIA.

To the Editor of the Paper Maker's Monthly Journal.

SIR,—In the concluding paragraph of my last letter, I proposed to, show "How Bamboo Paper Stock," produced under fairly favorable "conditions, can be brought into the market to compete with Esparto. both as to quality and cost."

1stly. As regards quality :—I have not shown the "Paper Stock" I have produced from Bamboo to a single paper maker who has not admitted its superiority to Esparto, both as regards its nominal strength, and the divisibility, fineness, and felting properties of its fibre : the raw dried stem also affords a much greater yield than Esparto, thereby demonstrating that it consists of more cellular tissue (generally termed cellulose) consequently not so much extraneous matter to get rid of, and it follows that less alkali is required for the boiling process, the boiled fibre bleaching as readily if not more so than Esparto,

Although it is well known that from time immemorial the bamboo has been employed for paper making by the Chinese, Japanese, and indeed more or less throughout India, hitherto only the old and matured stems have been used for such purpose, I do not pretend to say that paper, even of fair quality, cannot be made from the bamboo in this condition, but with age the stems naturally become woody, and can only be treated as the Chinese do by long continued maceration or destructive steeping or rotting, or as wood now is by high pressure boiling in strong caustic alkaline solutions, by which it is, like wood reduced to "pulp."

The system I adopt for producing fibrous "Paper Stock" is very different. I take the young herbaceous shoots or stems of the season's growth, cutting them while the sap is still flowing and before the silica, lignine, and other constituents of the sap have become deposited and indurated by age, passing them as freshly cut through crushing and slitting rolls, thereby abstracting much of the sappy matter; thus the pure fibre at this stage of growth is more readily and freely separated from these extraneous substances, and being produced in a *tow-like* condition by being willowed or teased out after boiling and washing, is, when dried, put up into hydraulic pressed bales for economy of freight (similar to cotton or jute), being ready for bleaching and the succeeding paper making processes when received by the manufacturer.

Having described the characteristics of the "Paper Stock" I propose to produce from the *young* bamboo, it may be well to point out the difference, both practically and commercially, between it and "pulp" resulting from the older stems.

In "pulp" then the cellular tissue existing in the old stems has by age been converted into ligneous tissue, in other words wood, and as remarked during such conversion the silica, lignine and other combined matters forming the substance of the stem have also become solidified and hardened, they therefore having to be got rid of, as it is only the true ligneous tissue which constitutes the "pulp," strong caustic alkali at an elevated temperature, *ergo* high pressure boiling, has to be resorted to render them soluble and removable, and as they form a very considerable portion by weight of the woody stems, it follows that the ultimate fibrous residue is considerably less than if the plant were taken in its young or herbaceous stage of growth, the fact being that the average yield of "pulp" from the old stems is only about 40 per cent. while that from the younger stems ranges from 60 to 70 per cent. (the results in either case being assessed from the stems when dried). In the old stems moreover certain coloring matters (as well as the silica and lignine) being deposited and fixed, even after boiling a more energetic and therefore more costly bleaching agency is required.

Neither is it possible to dry "pulp" so readily or so economically as the fibrous "Paper Stock," nor will it when dried pack into so small a bulk ; the freight and carriage charges, important items, are consequently more onerous.

So far, therefore, as regards the quality of bamboo "Paper Stock," of course I am aware that this, my statement, will only be accepted by many *cum grano*. I mean that as bamboo and the "Paper Stock" produced thereform is not as yet commercially known in the market it can only be judged by the somewhat limited trials I have made, the results of which may be seen from the specimens of paper and "Paper Stock" at the rooms of the Association.

However good or suitable the quality of any fibre may be, especially if proposed for paper-making, seeing the present low price at which paper has to be produced, the crucial question after all is cost, and unless this essential element can be brought within reasonable limits, success is hopeless.

The main, or rather the immediate difficulty, in this connection is that bamboo as a purely *raw* material cannot possibly be imported into this country on account of its bulk and lightness, and consequent cost for freight ; it follows therefore that it must be converted into "Stock" where it grows or is produced. In this respect however it only resembles other fibrous plants of an equally bulky nature (in their raw or natural condition), such as jute, flax, hemp, &c., from all of which the ultimate fibres as articles of commerce are produced by somewhat complicated processes, besides which such plants involve costly system of cultivation which the bamboo does not.

Growing extensively in most warm countries, the bamboo is essentially indigenous to the Tropics, and even there its most prolific growth is governed, or at least modified, by climatic influences, being, although not an aquatic, still a water-loving plant, and therefore flourishing best in a very moist climate, such for instance as British Burmah and the Tenasserim Provinces, the Straits of Malacca and the Islands of the Indian Archipelago. It abounds in South Western India and Ceylon, in most of the West India Islands, Central America, and the Brazils ; in China also and Japan it is most abundant ; in Southern India it forms in many districts dense and almost impenetrable jungles.

The bamboo is perennial, that is the parent stool or clump lasting many years, with most species from 50 to 60, when, having reached maturity, the plant flowers, seeds, and generally dies ; young plants then spring up from the seeds thus shed, forming the dense jungles or forests alluded to.

When the seeding occurs, which it frequently does over a wide district, the grain, somewhat like coarse rice, is eagerly collected by the natives, constituting a nutritive article of food.

The natural habit of the bamboo is that each clump or root-stock produces a growth of young shoots each year, from 8 to 10 or more, these being thrown up at the rainy season common to most tropical countries ; these shoots attain their full height in a few weeks, ranging according to the variety of the bamboo and the age of the parent stool, from 30 to 60 feet high or more (some species, *Bambusa Gigantea* for example attaining the height of 120 feet). If only a portion of these young season's shoots are cut, leaving say from one-fourth to one-third to maintain the vegetative functions of the plant, it will retain its natural vigour for a lengthened period.

From the foregoing it will be evident that an abundant, I may indeed say an illimitable supply of the raw fibrous material exists. I will consider in my next letter under what conditions this valuable paper-making material may be made available for the exigencies of our trade.

The Indian Agriculturist.

CALCUTTA, FEBRUARY 1, 1879.

THE MADRAS RYOTS.

"THE Blacker Pamphlet" tells us that the ryots of the Madras Presidency have been burdened by grievous over-assessments, and the author, Mr. H. A. D. Phillips, of the Bengal Civil Service, advocates the introduction of a permanent settlement. No fault is found with the ryotwari system *per se*: but the writer urges that the system has been abused by the Madras Government; who, in the matter of assessment and collections, have been judges in their own cause. The Bellary district is taken as an example of Madras settlements, and it is shown that the revenue demand has had to be reduced over and over again owing to over-assessment. The demand in Monro's time was 55 lakhs of rupees: in 1822 it had been reduced to 38 lakhs, and in 1857 to 34 lakhs. In 1874-75 it was only 25 lakhs. The writer shows that since 1857 there has been a more liberal policy, which was beginning to show its good effect previous to the famine: and he is of opinion that, if the present assessment, which he considers fair, were made permanent, 'the ryots would become a prosperous peasantry. The ryots pay in their revenue, direct to Government. They are, in fact simply zemindars: that they have remained petty zemindars, is due to the fact that high assessments and prohibitive rules have rendered the land of little value. For this reason, there are few large holders, notwithstanding the fact that there is every facility for obtaining land. It appears that more than half the total number of ryots pay less than Rs. 10, as annual revenue to Government. Though it is easy to obtain land, the opposition of the reddies or village-heads prevents it. The ryots are jealous of outsiders, and rather than let them take up land, they apply for it themselves, throwing it up after perhaps a year's cultivation. The exercise of this jealousy is facilitated by the rules of pre-emption, which hold in the allotment of land. "It is only by bribing the reddies," says the writer, "that land can be obtained, and they *par excellence* are interested in keeping out of the village, educated and influential outsiders, who might harm them by supplanting their influence, and bringing to light their numerous oppressions and peculations. It is easy for an official to say—"Let influential capitalists ignore reddies and tehsildars: we shall receive them with open arms, and give them as much land as they like to take." Can the outsider afford to ignore the village head? We all know the power of exaction possessed by a paltry process-peon on Rs. 6 a month. He is armed with Government authority: he is part and parcel of the *Sirkar*. What shall we say of the village reddie, who possesses magisterial powers and collects the revenues?"

The writer proceeds to give instances of many rules which bear hardly on the ryot, and throw obstacles in the way of improved cultivation. Formerly if a ryot grew a second crop on wet land, he was bound to pay the full assessment over again. "No wonder that double-cropping was a dangerous experiment. The second crop might prove a failure, and the cultivator would be a heavy loser. In this respect the Madras Government, which is in the position of a zemindar to the ryots, appears to have out-Heroded Herod, and to have surpassed the most wanton and extortionate exactions ever indulged in, by the much-abused landlords of Bengal." The rule has since been modified, and now a *Fasl jasti* of 50 per cent. is added to the assessment, if a second crop is sown. The writer points out that even this charge is indefensible; "Land is first assessed high, because it is near a tank; and then extra assessment is put on when the water is used. If the *Fasl jasti* be called a water-rate, then the land ought to be assessed as dry land: and the water-rate should be levied separately, as in the Godavery and Kistna deltas. To call the second crop assessment a water-rate, is absurd. A ryot pays a high wet assessment, because of the advantage he enjoys of being able to wet or irrigate his land. But if he *does* wet or irrigate his land, that is, if he uses the advantage which he possesses, then he must pay extra for it. The ryot thus pays twice over, for the same thing: he pays for his cake, and then he pays for eating it." The reason given for the paucity of wells is that formerly, land irrigated by private wells was assessed as wet land. Thus, there was no incentive to dig wells. Since 1860 only, the highest dry assessment has been charged, but the writer points out that no additional assessment whatever should be levied on account of new wells constructed by the ryots. Again,—the rules of remission, are very uncertain, and the taking up of new land is something very like gambling. "The following figures indicate that ryots in Madras may be crushed by heavy payments for waste land, perhaps rendered uncultivable by a bad season. In 1874-75, out of 2,211,777 acres, assessed at Rs. 25,38,251, which the ryots left waste out of their holdings, they were only allowed a remission of Rs. 2,66,552 on 77,067 acres. Again, in 1875-76, of the total area in ryots' holdings left uncultivated, 2,229,719 acres were charged, and the assessment thereon, Rs. 23,55,748 was included in the demand." The writer argues that the fact that the revenue demand has undergone gradual decrease, proves that the land assessment from the commencement was crushing, indeed overwhelming, or if this position be denied, the other horn of the dilemma must be chosen. "It has been shewn," the writer says, "that rents are even at the present day by no means low. They are perhaps fair. If something over twenty lakhs is now a fair demand, what shall be said of a demand of fifty lakhs seventy years ago."

Again:—a punitive assessment is imposed, if land be taken up without previous application. The writer shows that this rule often works hardly on the cultivator, as poor men with little capital naturally hang on as long as they can, to see if the season is likely to turn out favourable. "A propitious moment for ploughing or sowing comes, and there is no time to lose. It is hard to make a man dance attendance at the tehsildar's office, at such critical moments." The writer gives one remarkable proof of the former harshness of Government as the zemindar. It seems that ryots were constantly deserting the Government land, and cultivating inam lands which they were enabled to rent on very favourable terms. To prevent this, a tax called "inam ruffisk" was imposed on those who cultivated for inamdars. "This tax," says the writer, "was as great a shock to the security of private property as can well be imagined. In 1856, Mr. Pelly recommended its abolition, as it led to injurious interference, and urged that *if only the assessment were lowered, there would be no fear of ryots deserting Sirkar for inam land.* These remarks are worth dwelling on for a moment. Here were private landlords, actually taking less rent than the Government. Which was the exacting and extortionate zemindar—the inamdar or the Government? The fact is, as has been remarked above, that private landlords are actuated by motives of enlightened self-interest." The necessity for such a measure as the above, indicates that the back of the ryot had been broken by heavy assessments.

Mr. Phillips shows that whereas in Bengal custom and status have to a great extent been ousted by the advent of competition and contract, in Madras many customs had been stereotyped and given the force of law. It is urged that there are bad customs as well as good. The proposal to give greater power to village *punchayets*, is condemned in strong terms. "We are afraid these persons belong to the category of *laudatores temporis acti.*

The writer thinks that it is due to the permanent settlement that there has been no declared famine in Bengal this year. The price of food grains has in many districts been even higher than anything known in 1873-74. At such times, zemindars can do much good by executing private works, and underselling the banians. In Madras everything is left to Government. "At present," says the writer, "where is the class that could guarantee the interest on new railways, such as the zemindars of Patna, Gya, and Mymensing, have done. Leave the rents low: leave the ryots a large margin of profit, and such a class will speedily be created." The writer in another place says "an equable and fair assessment, rendered permanent, must result in the same good for Madras as it has for Bengal. The wealth of a Government lies in the wealth of its subjects: and if they be overburdened, cultivation is checked, and trade

cannot expand. As in Bengal, so in Madras, loss of land revenue will be amply repaid by increased receipts under other heads: by the increase of cultivation, the expansion of trade and commerce, the prosperity of the peasantry, and the creation of a wealthy and influential middle-class, which acts as a buffer between the Government and the masses. Then, and not till then, will the Government rest free from the nightmare of deficits and the horrors of famine."

We have given Mr. Phillips' views as fairly as it is possible we believe to state them; but it is strange that he should regard "a permanent" settlement, as the proper remedy for unduly high assessments. As a fact, the Madras assessments were intended to be permanent. If unduly heavy, they will crush the ryot, whether the assessment is permanent or annual. The right remedy is light assessments under leases subject to periodical revision. We believe the 30 years lease to be too long, in the true interests of all parties thereto, but the principle is right.

ARAKAN TOBACCO.

IT is very satisfactory to learn that as a result of the establishment of a Government Tobacco Farm in the Arakan Hills several maunds of unmanufactured tobacco cured on the spot have been despatched to the London and local markets for report. They will we trust elicit from the most competent and practical judges a careful and well matured opinion. Most of the tobacco was we understand grown on the Farm, and a large portion consists of leaf of a remarkably fine description raised from seed of the American and "Manilla" varieties introduced into the hills some years back. It was on leaf of this tobacco, but *cured* in their own rough way by the tribes, that Mr. Broughton, the Government Quinologist, Madras, reported in 1874:

"I have the honor to report on a sample of tobacco grown in "Northern Arakan. The tobacco yielded 23·45 per cent. ash. "This ash contained 8·59 per cent. of potassic carbonate. By "determination the tobacco was found to contain 1·95 per cent. of "nicotine. These results show that the tobacco contains important "constituents in amount closely resembling those which are the "most *favorite* tobaccos of European smokers, or the Havannah "and Manilla tobaccos of the English market. Like all the "tobaccos from British Burmah, its qualities are most encouraging "and show that its site of growth will produce tobacco quite "worthy of export. The sample sent is worth sending to the "Home market."

It cannot be expected that what has now been cured on the Farm will compete with the fragrant leaf of the West Indian and American varieties, which the experience and work of *years* has brought to such perfection, but we are sanguine that it will be found a good marketable product and admit after *manufacture* of a ready sale. The experiment will further demonstrate what has long been urged for the Arakan Hills, that a country possessing the climatic conditions and soil to yield tobacco of such luxuriant growth and size as that raised on the Farm this season (many of the leaves measuring 3 by 1½ feet) abounds with latent wealth, and as such offers special attractions to the capitalist. It would seem that the Arakan Hills are capable of great development. We understand that the application of an English gentleman for a grant of 2,000 acres in the vicinity of the Farm has been received very favourably by the Supreme Government. With order secured amongst the tribes, there is every reason to believe that the province will become one of the most important in the Empire. The permanent steam communication recently opened up between the hills and port of Akyab will greatly facilitate the importation of labor and the opening up of the hill country. If the Farm-cured tobacco be favourably reported on in the English market, it is worth consideration whether Government might not advantageously confine itself to buying up the leaf grown throughout the hills, and by improved curing, render it fit for home consumption. *This* however would lie more within the sphere of private enterprise, and should with the other established products, oil seeds, cotton, &c., afford ample room for the merchant pioneer of commerce. An epidemic of cholera on the Farm during the year together with the illness and absence of the Superintendent added considerably to the difficulties which attend most new projects at their outset, while the absence of all steady labor in a country with a population of only about fourteen to a square mile the greater part of the season, further restricted the operations. Notwithstanding these minor obstacles however, the Farm has been productive of much *indirect* good by giving an impetus to cultivation, and introducing new products which have induced immigrants to settle down in this locality, so that viewed on the whole it may be conceded to have amply secured the object of its establishment, and should by next year if it be continued, with efficient superintendence prove a financial success.

SUNN FLAX.

IN the Punjab, Sunn Flax is generally grown in narrow strips along the edges of fields of cotton or pulse, though in places in patches alone; it is generally sown about the month of April and irrigated up to the rains, though some cultivators sow it just after the first shower in June; the April sowing gives the best result. About the end of August or beginning of September the plant flowers, and will be from 6 to 9 feet in height. If fine soft fibre is required, cut the stalks while still in flower; if strength (for cordage, &c.), when the seed is formed, but just before it ripens. The plants are either cut, or pulled up by the roots like ordinary flax; the former method is preferable, the operation being done with a native sickle. After being cut the stalks are steeped—in clean water, if possible—the duration being dependant on the season of the year, and climate. In August or September—in warm situations—2 or 3 days are sufficient for the fine soft fibre, but from 6 to 8 days if required for strength, and the completion of the process is known by the readiness with which the bark separates. When ready, the labourers take up the stalks, lay them in hand-bundles on the bank, and then take them up in handfuls by one end, and beat them on the water to remove the glutinous matter from the fibre; the stalks are then turned end for end and again treated in the same manner, after which the fibre is washed, the pith removed, and hung up on branches of trees to dry. The sap and vegetable matters should be separated from the fibre as quickly as possible, as it is the fermentation of these substances that hastens the decay and consequent weakening of the manufactured article. The object of steeping is to separate the bark from the woody part of the stem by dissolving the glutinous matter which causes it to adhere, and also destroying some minute vessels which are interwoven with the longitudinal fibres and keep them together in a kind of web. *A certain fermentation or incipient putrefaction is excited by the steeping, which must be carefully watched and stopped at the right time, or the fibres will become rotten.* It takes about 25 seers (50lbs.) of seed to sow an acre, and it is believed that an acre will yield between eight and nine maunds (80lbs. to the maund).

Sunn flax thrives best in a high and dry situation; a clayey, low-lying soil is bad, while too rich a soil produces coarse fibres. It is cultivated up to an elevation of 2,500 feet above sea-level, and is grown all over India. In Travancore it is called *Wakunnar* in Bengal, *Biljanjan*, and in the Punjab, *Niha sunn*. It is produced in large quantities in the neighbourhood of Jubbulpore. Locality and climate slightly change the growth, but all belong to one and the same plant, *viz.*, the *Crotalaria juncea*. It is very similar to the Spanish Broom *Spartium junceum*, well-known in England for the tough fibrous nature of its branch twigs It should not be mistaken for the *Hibiscus cannabinus* (Vern. *sankokra patsan*) which is inferior in strength. It is sometimes called the female of the *Hibiscus cannabinus*. It is exported to Europe under the names of Bombay hemp, brown hemp, Concanee hemp, Salsette hemp, &c. The fibre is used for cordage, fishing nets, ropes, strong packing-cloth, stout gunny-cloth, &c., and it is preferable to Russian flax for spinning. It has been tested up to a strain of 170 lbs. without breaking.

Dr. Royle, in his *Fibrous Plants of India*, gives some interesting particulars about Sunn flax. The earliest treatise on the Sunn plant was written by Wisset in 1804. The seeds are officinal—used to purify the blood in special diseases. It belongs to the N. O. *Leguminosæ*: the seeds are flat, irregular in shape, oval or triangular, deep concave, surface smooth, or with one or two ridges; color, pale yellow to deep brown. Though called hemp, its has no connection with the true hemp *cannabis Indica*. A simple description of machinery would cheapen the present cost of preparation.

THE BANGALORE EXPERIMENTAL FARM.

AFTER not quite four years of more or less successful existence, the experimental Station at Bangalore is to be closed. I use the word Station advisedly, as it is better understood than the term *Farm*, which has a commercial ring in it, and I would suggest its adoption to all scientific agriculturists, who may be at any time engaged in endeavours to improve the agriculture of this country. Farms, so called model, have fallen into disrepute with the Indian public, being too much in advance of the capacity of the native farmer to appreciate.

Model Farms, cultivated in the very best manner, are institutions which can only be of use where the community, for whose benefit they are designed, is sufficiently free from the prejudices of custom, superstition, and ignorance, which are so strongly developed in the Indian ryot, to be able and willing to adopt anything out of the common, which it may see anywhere adopted with profitable results. When education has reached the cultivating classes of this country; when science has by her enlightening influences aided in dispelling the clouds of superstition; and when time-honored custom is no longer the hard and fast rule of the farmer of our national properties; then perhaps Model Farms will serve a useful purpose. Until then all those interested in Indian agriculture had better, I believe, bury the term in oblivion, and endeavour to wipe out the memory of past failures; failures though they be owing simply to the misguided endeavours of civilian amateurs. Nothing should be left, if possible, to allow of such futile and ill-directed attempts being confounded with the movement which has of late years commenced in Madras, and which is now surging northwards rapidly. Bombay having decided on following the example of the Southern Presidency, and in no mean or half-hearted manner: let us hope that ere long Bengal will relieve herself of the reproach of being one of the last to see in what lies the true interests of the country and the people.

But to return to the Bangalore Station, of which I sent you a short description some months ago. It is to be closed as soon as Mr. Harman, the Superintendent, can be got rid of, which is not an easy matter, unless it be true, as is reported, that that gentleman is going to take up a professorship of Agriculture in the Poonah College. The only satisfactory part of this change is the sphere of extended usefulness to which Mr. Harman will be transferred; coming to his new post with several years of Indian experience, he will start on more advantageous terms than it has yet been possible for any agriculturist to do, and no doubt will ere long be able to feel the satisfaction of having made some real progress in educating the public on agricultural topics.

The waste of public money in closing such an institution as that at Bangalore, after so short, and what has been on the whole so satisfactory a trial, is and must be great, for in preparing such a place for experimental work, much labor and expense had to be incurred, the return of which is doubtful *now*. Why in a country just recovering from famine, and therefore all the more necessitous of an improved system of husbandry, it should be one of the first to suffer retrenchments, is a matter of mystery to any one, who is not aware of the pitch to which the penny-wise and pound-foolish policy is carried in this country. The money, so often wasted, or, if not actually wasted, ill spent in irrigation works of doubtful value, would do far more real good, and tend to a far more stable prosperity, if spent in well-devised, and strenuously executed measures of agricultural reform. It is to be feared that the money saved (?) by closing the Bangalore Station may be spent on the manufacture of tanks, for the extension of the growth of the worst crop, in every respect, cultivated in Southern India—namely, paddy, a crop only fitted for growth in malarious swamps, and pestiferous deltas.

With such a specimen of their obtuseness before us what can we expect the Government of India to do themselves, with a view to improve the condition of the ryots. The latter illiterate; ignorant of almost every thing, but what has been time-honored, as regards farming; superstitious to an almost incredible degree; sunk almost hopelessly into debt under the hands of ravenous usurers; permitted to treat national property, in the shape of the soil they cultivate, just as they in their ignorance please; is it surprising that the country is retrograding in agricultural prosperity at a pace, which increasing year by year and season by season, must before long, unless measures wide-reaching and well carried out are put in execution, must, I say, soon land the country in irretrievable bankruptcy? The soil is India's sole source of wealth at present—the source of her revenue, and will if the treatment of it which has been allowed to go on unchecked until now, is not put a stop to, be the source of her ruin. Called upon to support an increasing population, less and less manured year by year, cultivated with an implement which can but scratch, is it likely that the soil can long continue to pay the rents which are put upon it? And yet our rulers do not make any move in the matter except backwards. It is time that all who have the real interests of India at heart—and in her interests agriculture holds the foremost place—should combine to press on Government the urgency of the need, the greatness of the danger of delay, the necessity for immediate action. The time has come when the public should make their voice heard, and should; do our rulers decline to open their eyes to the danger, make what efforts they can on their own behalf to arrest the evil. Nothing effective can be done until the Legislature steps in to stop indiscriminate and ill-guided cultivation; to relieve the burden of debt; and set its face against the practice of entertaining tenants on Government lands, who have not the requisite capital to conduct the cultivation of the lands they hold in a fitting manner.

AGRICOLA.

6th January, 1879.

EDITORIAL NOTES.

WE have before us an interesting sign of the progressiveness of the age in the form of a pamphlet entitled the *Kaira Agricultural Record*, being the first of a series of papers it is intended to circulate among the agricultural classes by "The Committee for the Encouragement of Practical Agriculture" at Neriad in Guzerat. The brochure forwarded to us is an English translation from the Guzeratee. In the course of some introductory remarks we are told that it is to encourage the spirit of enquiry that impoverished lands and decreasing returns have aroused amongst the cultivating classes that this committee has been formed: "We have done what we could with the means at our disposal. As no agricultural education is available in this Presidency, we have sent some of our Patidar lads to study in the Madras College, hoping that the information which they will there acquire will be of use hereafter to the cultivators of this district. We have also arranged for the supply of the ploughs which have been most successful in Madras, and we have sent a practical man to the Madras Farm to receive instruction in the use of those implements. Some experiments have also been made in the manufacture of bone-dust for manure."

This is most gratifying news: pregnant with promise of a bright future, and we earnestly hope that the Neriad reformers will not be discouraged by the small difficulties that will beset their path at the outset. Let them but have their heart in the work, and persevere with it, and the benefits they will confer upon Western India and the country at large are inestimable. The immediate object of the society is to distribute in a popular form simple information that will be of practical use to the cultivators, and to encourage the ryots to seek knowledge. This first part consists of an account of Mr. Robertson's recent visit to Neriad, and includes some useful hints on the subject of ploughing and manuring. In some of the land examined by Mr. Robertson "pits had already been dug at the instance of the committee, and were deepened by Mr. Robertson's direction and the sub-soil examined. The result of this examination was astonishing. *Rich virgin soil, which had never before seen the light of day*, was stirred at every stroke of the spade, and when these experiments were repeated with precisely similar results in other fields, Mr. Robertson told us that we were happy in the possession of some of the finest soil he had ever seen." In the next issue of the *Record* we are promised a paper on the subject of the use of male buffaloes for agricultural operations in Guzerat, and we are pleased to see that a prize of Rs. 50 has been offered by one of the members of the committee for the best pair of male buffaloes trained for ploughing.

WE have not yet found time to notice Mr. Digby's two admirable volumes, on the Madras famine. We are obliged however to

dissent from certain of his conclusions, and hope to find an early opportunity of reviewing them. Thus he evidently entertains the belief which actuated the Supreme Government throughout the famine, that "the merest suspicion that the Government intended "to enter the market, would instantly paralyse the private trade. "No human being within the district which the Government had "taken as its sphere would ever obtain a pound of food save from "Government stores so long as the famine lasted. And this it is "which renders the question of Indian famines so profoundly "embarrassing. The grain trade does really, under particular "circumstances, fail to fill a space which the Government is "bound to occupy; but if it occupies this void a minute to soon, "or takes this necessary step with an amount of ostentation "which causes its purpose to be misconstrued, it instantly destroys "a power, on the whole vastly more valuable and efficient than its "own, and ends by starving its tens of thousands where it meant "to feed its thousands."

It is sheer delusion. The facts disprove the belief absolutely, but in India, we are accustomed at once to reply, "so much the worse for the facts." We have seen over and over again, that the certainty of high prices is all the stimulus that is needed, to set as much private enterprise in motion, as the country will yield. The fact that the Government poured 400,000 tons of food into Behar, in 1873-74 did not arrest for an instant, the pouring in of another 400,000 tons by private enterprise from the Punjab and Upper India. We have encountered but one famine as yet successfully, while so strong are ancient prejudices and mental pre-occupations upon the subject, that the very measures which were then successful, would have failed to a certainty, we are told, in Madras. Why should they have failed there, any more than in Behar? The strength of traditions and prejudices amongst officials in this country, is overwhelming.

The Act that was passed last Session of Parliament called the "Weights and Measures Act, 1878," came into operation on the 1st of January. The great object of the Act, is to secure uniformity of weights and measures throughout the United Kingdom, where notwithstanding the imperial standards, the confusion that prevails is almost as great as in this country. Local measures have hitherto held their ground, against every attempt to introduce uniformity. Not only was there no uniformity in the unit of measure, but "quarters," "bushels," "hundred-weights" "bolls," or "sacks" meant different measures in different places. The confusion in weights was almost as great, and it was with a view to rectify these anomalies, that the Act of last Session was passed. From the 1st of the present month, according to the 23rd and 24th clauses of this Act :—

"Any person who prints, and any clerk of a market or other person who makes, any return price list, price current, or any journal or other paper containing price list, or price current, in which the denomination weights and measures quoted, or referred to, denotes or implies a greater or less weight or measure than is denoted or implied by the same denomination of the imperial weights and measures under this Act, shall be liable to a fine not exceeding 10s. for every copy of every such return, price list, price current, journal, or other paper which he publishes.

"Every person who uses or has in his possession for use for trade, a weight or measure, which is not of the denomination of some Board of Trade standard, shall be liable to a fine not exceeding £5; or in the case of a second offence £10 and the weight or measure shall be liable to be forfeited."

It is now illegal in England, to use any weight which is not some fraction or multiple of the imperial pound, any measure of length not derived from the standard yard, or any measure of weight or capacity, not derived from the imperial standard pound. "Heaped measure" is abolished, and the vessel only filled to the brim. The existing sub-divisions of the pound measure are to be of course retained, and no change is made in Troy and apothecaries' weight. The law is aimed at the local customs of trade. Bargains in any but imperial weights and measures are now illegal, and subject to a fine of 40s. for every sale made. Local standards are to be provided by the Board of Trade and are to be subject to verification at least once in five years.

Now if Mr. Whitley Stokes instead of spending his strength upon the framing of new Legislative Acts, that only bewilder the people, encumber the Statute Book, and fill the Courts with new litigation, would take up the long neglected subject of Indian weights and measures, he might leave behind him grateful memories in India. The first step would be to measure the extent of the evil, and it is almost infinite. We shew ourselves at times as timid in our legislation, as we are generally rash and hasty. We believe that we might long since have dealt with the great evil under notice, with the strong sympathy and approval of the people.

The disappearance of the usury laws from the Indian Statute Book, is we observe being commented upon at home. Mr. St. George Tucker writes to the *Times*, that the mistake which our Legislature has made, has been the compelling of our civil courts to aid and abet the usurer. Indian judges have been denied the liberty of modifying usurious contracts. Sir George Campbell, when head of the judicial administration in Oude, limited interest to be decreed, to 50 per cent. of the principal; but the bond, the whole bond, and nothing but the bond is considered to be the perfection of civil court wisdom in India, as a rule.

"The Parliament of Roumania is showing an example of wise legislation by placing restrictions on the alienation of land. After the rebellion in Oude had been suppressed in 1858, the Government determined to authorize the barons or great talookdars to give away, sell, or devise their estates at their pleasure. So distasteful was this to noblemen whom Government wished to honour, and on whom it fancied that it was conferring valuable privileges, that in January 1862, almost all the chiefs of Rajpoot clans, advised by Rajah Hunwunt Singh of Dharoopore and Rolakonkur, signed a petition to his Excellency the Viceroy humbly begging that the supposed boon might not be conferred on their families, but, on the contrary, that any alienation of their lands should be restricted by Hindoo laws and by ancient customs, in accordance with which the noble Rohuttrees had held the greater part of the Gangetic valley for hundreds of years."

Every official in India, down to the assistant magistrate, knows that our civil courts have become hateful to the masses of our Indian subjects, because those courts have become the tools of the rapacity of the usurer. Mr. Robert H. Elliott very opportunely points out the practice in the Nizam's Civil Courts in the words of a native official.

"By our civil laws, our ryots are protected as far as possible from money-lenders, for in our courts a mere execution of the bond on which the claim rests, does not make a contending, or absent debtor, liable for the amount sued for, until the creditor should have proved to the satisfaction of the court the consideration for which the bond is executed. And if, on going over the accounts, it is found that a usurious rate of interest has been charged, the court at once reduces it to a reasonable rate. In the execution of a decree against the property of a ryot, his house, his agricultural implements, and a supply of grain sufficient to keep him and his family for six months are exempted from attachment, and this wise measure saves the cultivator from beggary and ruin. In these days of reforms and innovations, I earnestly hope and trust that this wise and beneficent rule will not be meddled with."

Thus in the Nizam's dominions, a peasant is recognized as a child, and treated accordingly. In our own districts, he is regarded as if he were an Englishman with a lawyer at command. When the ryot comes to complain that he is in difficulties through his ignorance of the low, we tell him, "*Ignorantia juris non excusat.*" If this does not satisfy him, we tell him of the law of *caveat emptor*, and so on. No one could speak more bitterly of the existing law than our judges themselves. "The Civil Courts" says one of them "often become the direct cause of the cultivator's misery." There is something radically wrong with our administrative system, when no remedy can be applied by us to evils universally admitted and which are clearly susceptible of modification. Here again is work for Mr. Whitely Stookes of the right order.

The office of Superintendent of the Botanical Gardens and Parks on the Neilgherries, extracts from whose last annual report we print below, is no sinecure. Mr. Jamieson has charge of the Ooty Garden, the Medicinal Garden, Upper Norwood, Stonehouse Park, Sunning Dale, Sim's Park, Burliar and Kulhutti gardens. The gross receipts of the Government gardens were Rs. 2,987-10-3. The Government very properly suggest that the seeds available in the gardens should be regularly advertised for sale in the newspapers, and that the public should be put in early and full possession of the results of experience gained in the cultivation of the

Liberian and West Indian coffee plants, with a history of the treatment of the plants and full particulars as to growth, &c. We hope that the wishes of Government will be carried out. The medicinal gardens where the jalap, ipecacuanha and other plants grow, promise to be successful. At Burliar the ipecacuanha plants thrive under partial shade. Sim's Park, established in honor of the late senior member of the Madras Council, is doing well, the expenditure in the year 1877-78 having been Rs. 2,589. The Kulhutti gardens were not remunerative; the sale proceeds of the plants were small, and Mr. Jamieson recommends that the plantation be sold. It is thought that Sim's Park, which is progressing most satisfactorily, will need all the time and attention that the superintendent can devote to it.

A Rangoon correspondent tells us that the Olive has just been discovered growing wild in groves, in British Burmah, by Mr. C. G. Forbes, Deputy Commissioner of the Tharawaddy district. Should this information be confirmed, it will be very important. These wild olives are said to flourish luxuriantly in many parts of the new district of Tharawaddy. The tree appears to be of much more rapid growth than the Italian tree, for while the latter takes from twelve to fifteen years to come to maturity, this Burmese species fruits after three years, and the fact that groves of these trees are growing wild in the plains near Thongzai, exposed to the great heats of March and April and to the heavy monsoon rains, proves that they are very hardy. The strange thing is that we have not heard of them before. It seems that the Burmese make a pickle out of the fruit with salt and water, but it is thought it would answer admirably for oil. If such is the case, and the necessary machinery is set up, Burmah may soon be able to add a new and valuable product to her list of exports. The Irrawaddy Valley Railway passes within a few miles of these wild olive groves, so that every facility can be had for bringing the fruit or the oil to Rangoon. Townsend tells us that the olive is indigenous to China, whence it was imported to Europe so early as 1771.

In Mr. Benson's report for the year 1877-78 of the Agricultural School at Sydapet, the cost of the institution is stated as follows:—

		Rs.	A.	P.
Ordinary charges.	Lecture fees, master's salaries and wages of establishment	8 791	5	9
	Stipends and scholarships to students ...	3,[illegible]00	0	0
	Contingent expenses	1,652	15	5
		14,017	5	2
Extraordinary expenses, including the provision of quarters for students		5,868	14	1
	Total ...	19,916	3	3

In November last Mr. Benson wrote to the Board of Revenue that as the Government have issued orders for the admission of a fresh class of students, the cost during the coming year will be increased: "I estimate, as far as ignorance of the intentions of Government will allow, that the ordinary expenses of the college will be about Rs. 20,500. The cost of conducting the institution in future will depend on the adoption or otherwise of the recommendation of the Board to appoint special Professors of Chemistry and Natural History. If also a scheme for the provision of elementary agricultural instruction in the districts, be developed, it will be possible, when it is in work, to reduce the length of the present curriculum of the College here, which has been designed to be the Central Institution for the whole Presidency, from three years to two." The Board in forwarding the above to Government have pointed out that their proposal was not to constitute two additional professorships, but to procure two qualified agriculturists to take charge of the district farms, employing them as lecturers in any subject which they might be competent to teach during their stay at Sydapet, whilst learning their duties. As the School of Agriculture is likely to become a permanent institution, the Board of Revenue have asked the Superintendent to submit year by year a budget estimate in regular form.

In reply to an enquiry from Mr. Benson, regarding the number of stipendiary studentships and scholarships which it is intended to offer to the class about to be taken in, the Madras Government observe that it was never intended to maintain the number of stipendiary studentships after the first class at twenty-four, and no reference at all to the subject appears to have been made in the prospectus issued in September last inviting a fresh class. At the same time the students now admitted may with reason have anticipated that some such assistance would be afforded; and the number for this class at all events will be fixed at fifteen, but the stipends will be slightly reduced and be Rs. 10 for the first six months, Rs. 12 for the second year of training, and Rs. 15 during the remaining nine months, *i.e.*, until the close of the final session. The scholarships will remain at their present amount, but like the stipends will not be paid after the course of instruction is concluded. The cost of these benefits for the entire period of training will thus be as follows:—

15	Stipends at Rs.	10 each, for	6 months	...	Rs.	900
15	" " "	12 " "	12 "	...	"	2,160
15	" " "	15 " "	9 "	...	"	2,025
3	Scholarships " "	10 " "	21 "	...	"	630
			Total	...	Rs.	5,715

The Government gather that the funds likely to be at the disposal of Government for agricultural purposes will bear these charges, but it must be borne in mind that when the full number of three classes is admitted, the charges for lectures will grow materially.

We quoted a statement from the *Brewer's Guardian* in our last, that maize has been successfully malted, and we are now told that not only maize but paddy, has been successfully malted at the Arvenghaut brewery. The difficulty of procuring barley on the hills is very great. When the Government insisted upon barley malt alone being used in the manufacture of Neilgherry beer, they overlooked the fact that the produce of barley on the hills is insignificant, and much of this small home growth is not accessible to the brewer, because the bucrgher cultivator consumes it himself. However, the restriction to barley malt has been withdrawn. Maize grows remarkably well in all parts of the hills, the elevation of which is not over 6,000 feet. Some of the cobs produced at Coonoor from American seed are said to have been 'superb.'

The difference that aspect and climatic influences exercise upon agricultural and horticultural produce is powerfully exemplified in the appearance, at this time of year, of the orchards of Messrs. Misquith and Frend at Ootacamund. These gardens are only two miles apart as the crow flies; the former has a southern aspect, and is at present rapidly maturing its fruit, while the latter with a northern aspect is wintering, and there is but the faintest semblance of the coming blossom. Mr. Misquith's fruit comes in about March and continues till May, when Mr. Frend's is only just beginning to ripen. Both gardens are about the same elevation. Mr. Misquith's experiences the greater share of the north-east monsoon, while Mr. Frend's gets the worst of the south-west.

Mr. Maclean, the Collector of Customs, in his report on the trade of Calcutta for the last official year, attempts to explain the great increase which has recently occurred in the trade in myrabolams: "The tanning trade usually consumes a considerable quantity of oak bark and acorn-cups from the Baltic. The derangement of Russian trade in consequence of the war, led probably to this supply not being available, and therefore consumers supplied themselves with myrabolams from India, where the crop was large." The explanation seems satisfactory on the face, but the fact is that the only effect of the war on the Russian export trade, was to divert the exports from the Black Sea to the Baltic whence there was a much larger trade than usual, while the war lasted. The real cause of the sudden increase in a trade, which has for some time been rising in importance, would appear rather to be the interruption in the supply of valonia and of galls (valonia being the acorn-cups of *Quercus Ægilops*) from Turkey and the Levant. These articles are largely used in France and in England for dyeing, tanning, and making ink, and the source of supply is the coasts of the Levant. Myrabolams will not improbably become a staple article in Indian trade. They are the fruit of certain kinds of terminalia, abounding in the Central Provinces, and parts of Madras and Bombay. When the railway is open from Nagpore to Chuttisgurh, there will be a great development of the trade, for the forests of those tracts produce a practically inexhaustible supply. The country is at present almost inaccessible.

An Agricultural Meeting and Cattle Fair will be held at Songarh, Kattywar, on 13th, 14th and 15th of this month. The subject we are told, has been taken up warmly by the chiefs and people of the neighbourhood, and also by many influential outsiders. There is every reason, therefore, to hope that the success of the Songarh meeting will even exceed that of the previous similar undertakings of Major H. L. Nutt, President of the Committee at Wudhwan and Toondla. We believe it is intended to make the coming Agricultural Meeting a thoroughly practical gathering and not a mere *tamasha*. To this end there will not only be ploughing matches, but suitable lectures are to be delivered. The class for poultry is a new feature in these exhibitions. Seeing how largely the domestic fowl is made use of in this country, and how poor the quality it is perhaps a matter of surprise that efforts to improve the breed, such as Major Nutt now proposes to make, have not been made before.

It is understood that Mr. Croft, the Director of Public Instruction, has his attention directed to the provision of Agricultural Schools in Bengal. Bombay has moved in advance of Bengal in this matter, but Sir Ashley Eden's rule will be signalized we hope, by the commencement of agricultural, as well as technical, education in those provinces. But for the unfortunate year 1873, Sir George Campbell would in all likelihood have had one or two Agricultural Colleges opened in 1874. If the local Government has any project of the kind under consideration, it could hardly do better, we think, than do as Sir Richard Temple did, write to Mr. Robertson of Madras to visit us for a month or two, that the Director of Public Instruction and the Secretariat may consult with him, as to the steps to be taken to initiate the experiment. Mr. Hurry Mohun Mookerjee submitted a scheme for the formation of agricultural classes in the existing Bengal Schools a month or two ago to the Director, but what has come of it we have not heard. Mr. Mookerjee's scheme is a very modest one, and might be submitted perhaps for Mr. Robertson's opinion. Mr. Mookerjee is, we believe, both a practical and scientific agriculturist,—perhaps the only one in Bengal.

The representative of the Republic of Guatemala at Paris has been endeavouring to introduce into the Old World, some of the less known natural products of the New; and among them he specially recommends a species of sage (*salvia chio*), which is said to be highly appreciated for its medicinal qualities, as well as for its aromatic flavour, among the inhabitants of Guatemala, where it is known as "chave." It is an annual plant growing in temperate districts, and flourishing, without requiring any attention, by the roadway or on the edges of ponds and pools of water. Its chief characteristic is in the abundance of seed which it produces, which affords a material for making a very refreshing non-intoxicating beverage. The seeds are exceedingly mucilaginous, and when mixed with water, the fluid is easily extracted, forming a delicious liquid which is much sought after as a popular drink, especially during very hot weather. The seeds are valuable also, as producing a quantity of clear, and almost colourless, oil, which dries very rapidly, and which, it is suggested, would be useful for the mixing of oil-colours. Little or no attention, however, is paid to the cultivation of the plant, or to the extraction of the juices and oils which are yielded by its seeds. As it is readily propagated from seed, there should be no difficulty in testing the practicability of its growth in this country.

What has become of Dr. Helfer's model plantation at Mergui? He and his wife some years after the first Burmese war made a tour through the Southern portion of British Burmah, Dr. Helfer having been commissioned by the Government to explore and report upon the newly acquired territory. In these reports, a translation of which has been recently published, he speaks highly of the natural resources of the province. He was the first who discovered coal on the banks of a tributary of the Tenasserim, and loadstone at a place near the Salween river, believed by the Karens to be haunted by gnomes who permit no man who intrudes upon its sacred summit to leave it. No part of the book surpasses in interest the account of Dr. Helfer's model plantation at Mergui which Madame Helfer strove with characteristic spirit by the help of her brother to keep up after her husband's death. The Board of Directors however in accordance with the spirit of those days refused to give a grant of the land, although it was strongly urged by Lord Auckland, the then Governor-General, and the plantation had to be given up by Madame Helfer, who returned to Europe.

The fact is now pretty well established that should grapes fail, we have an excellent substitute in oranges for the manufacture of wine. A French paper states that four different kinds of wines have already been obtained from the latter fruit, one called imperial, and a dry wine from the fruits produced in January; mandarin from those of April, and a sparkling wine, by a special process, possessing a little more than 12 per cent. of alcohol. The fruit is made use of before it is fully ripe. Growing so plentifully as the orange does in parts of India, Nagpore and Sylhet for instance, we may hope to see good wine produced in this country before many years have passed.

The results of the analyses of some of the Ceylon soils made by Mr. Hughes have been published, including those of Kahagalla, Wiharagalla and Kalupalani in the Haputale district, and a number of estates in the Dimbula district. In the case of the Haputale soils some disappointment is felt by the planters in that district at the results of the analyses, and at Mr. Hughes' remarks thereon, no cause for the dying out of coffee being given, but Mr. E. G. Harding writes to the *Ceylon Observer*, suggesting that the dying of trees even in such rich soils as those in Haputale may be accounted for by their roots coming in contact with some poisonous substance, such as peroxide of iron, and that deep draining may prove effectual as a cure. The results of the analyses of the Dimbula soils have also given surprise, but of an agreeable nature, for they turn out to be some of the richest in Ceylon.

From statistics before us, we find that the acreage in Bengal under jute this season exceeds the amount last year in the district of Buckergunge by 40,000 acres, in Furreedpore by 41,000 acres, in Rajshaye by 27,000 acres, and elsewhere by 10,000 acres; whilst in Pubna and two or three other districts on the Pudda river, there has been a decrease of 37,000 acres owing to want of rain, and the transference of land hitherto employed for jute to the production of cereals.

Mr. R. Hember, of Queen Charlton, Keynsham, near Bristol writes of some important experiments in a letter addressed to Mr. Eastmead, of the Crowle Charring and Condensing Company, on the nature and value of charcoal as a basis for manures:—"I am fully satisfied that as a basis for manure charcoal will be greatly appreciated when it is more generally known. I am a great believer in charcoal myself, having taken a hint when quite a lad working upon my father's farm at "stifle burning." I noticed how much better the ashes were when burnt black, or only charred, than those that were over burnt or burnt red. Those black ashes saturated with the runnings of a dung heap or stable used to be a very favourite garden manure, the results being so much better when the 'burnbake,' as we used to call it, was used, than when the liquid alone was used. This gave me a great idea of black burn-bake, which I considered a species of charcoal; and for eighteen years I made artificial manures for my own use, and the last five years for sale to customers. I have used charcoal with the very best result. I could relate many surprising results from mixing charcoal with artificial manures, and you will find you have much to learn yet of the good effects of charcoal. I am trying experiments every season on my farm, which is 300 acres, so that I have an opportunity of judging of its effects upon the different crops, and I carefully note its effects upon my customers' crops. Most of them tell me that they never saw such results from any manure, and that they could not believe that any manure whatever, could make such a difference. I attribute my success entirely to a suitable admixture of charcoal. It is a great cleanser and storer of ammonia, and there is more in it than any of us know of yet. Many objectionable plants will be found to disappear entirely by a few applications. It will quickly remove moss and things of that kind; and, from appearance, I believe it to be proof against smut and blight in corn crops. I do not sow or prepare seed corn in any way, but sow it simply as it is, and I do not see any smut or

blight of any kind. The manure seems to have a great cleansing and invigorating effect."

The *Rangoon Gazette* says that the Toungoo Missionaries are about to try their hand at sheep farming among the Karens. If we are not mistaken they tried the experiment some years ago. The Government made over a number of sheep to one of the missionaries for distribution amoung the Karen villagers, but the result does not appear to have been successful. Sir Ashley Eden when Chief Commissioner took great interest in the attempt to introduce sheep breeding in the Province. Shepherds were sent over from Bengal and farms were established in the Prome and Thayetmyo districts, but the project failed, the farms were broken up, and the sheep made over to the villagers; but most of the sheep died. No doubt, sheep breeding would succeed in certain places in Burmah under competent European management.

From a recent issue of the *Journal of Applied Science*, we obtain some interesting particulars of the cultivation and manufacture of indigo in Salvador. This, the most important product of the Republic, is still classed in Europe under the name of Guatemala indigo. In the country it is usually called *jiquilite*. It grows anywhere, but it is generally sown in ground prepared beforehand. The soil, according to its geological composition, produces different results in the indigo. Thus, at the foot of the volcano of San Savaldor, half a pound of dye is sometimes obtained per load of leaf; at Santa Barbar, the property of General Gonzalez, and at Santa Cruz, which is situated at some distance from the sea, thirteen to fourteen ounces are obtained. Nearly all Salvador is covered with jiquilite, forming fields of verdure, and furnishing rich products to its agricultural industry. The localities where the jiquilite is grown are called *manchones*. The workmen (*sacateros*) cut the plant with a small sickle, and form it into sheaves of fifty to sixty pounds; four of these latter form a load of eight to ten arrobas. The jiquilite is thrown into vats called *obraics*. Each pile of twenty-five loads requires two vats, and the maceration lasts from twelve to seventeen hours, according to the temperature and composition of the water. When the liquid is in a state of fermentation, the colouring matter is drawn off into another vat, where it is beaten by means of wooden wheels, and then the dye is precipitated by the sap contained in the bark of the *Tihuilate* (*Yonidium*) of the Platanillo (*Myrosma Indica*, or of the Cuaja tinta; these plants have no acid reaction. When once the dye is precipitated, it is allowed to settle during the night, and the following day it is boiled, filtered, pressed, and lastly dried in the sun. Every bale or suron contains 150 pounds. The different grades of indigo are specified by numbers. From four to six, ordinary; seven to nine, fine or superior. The first numbers correspond with what are called "Cortes" and the second "Sobresalientes." Salvador generally produces nearly 2,400,000 pounds. With better apparatus the grades would be superior and the product more abundant. San Salvador exports annually 14,000 to 15,000 surons of 150 pounds each, which represent an approximate value of 1,721,378 piastres or dollars. The superior indigo is sold in the fairs of the country at about eight reals the pound; the lower grades vary between three and five reals the pound. The produce of the superior grades costs on an average $1·25 the pound, on board steamer; numbers seven and eight, one piastre the pound; and number six, seventy-five centavos (3*s.*) per pound. In the European markets, the prices vary according to the crop of the preceding year, and the larger or smaller production of indigo in India, with which it has to compete.

The *Behar Herald* says "the Sarun Irrigation scheme introduced during the last year is of a somewhat novel financial character, It is based on a local guarantee of the interest on the capital outlay. It consists of a canal by which water from the Gunduck will be thrown into the principal water-courses of the district, from whence it will be distributed at the cost of the people themselves for irrigation and manufacturing purposes. The estimated cost is five lakhs, 4½ per cent. on which has been guaranteed by a few of the principal planters and zemindars, the Government remaining responsible for the cost of maintenance, and recouping itself from the proceeds of the sale of all surplus water for irrigation, the guarantors having priority of right to a supply. Some progress was made with some of the supply-cuts during the year, and it is hoped that the works will be finished before the rains of 1879."

The Rev. L. St. Cyr of Dindigul has for many years maintained a very useful establishment, an Agricultural Orphanage, for native children at Dindigul. The orphanage buildings, which are intended for the accommodation of 50 children only, were found insufficient for the increased numbers maintained during the famine year, and had to be enlarged at a cost of about Rs. 1,000. The cost of the buildings and the increased cost of maintaining so many children press heavily upon the slender resources of Mr. St. Cyr; he therefore appeals to Government for a grant-in-aid of the building outlay. The Governor in Council has replied, that the curtailment of famine expenditure places it beyond his power now to make any further grant of the character of that applied for by Mr. St. Cyr.

A contemporary draws attention to a new value for geraniums. In South Africa, we are told, the geranium has the reputation of being proof against snakes, which it is said, avoid the plant as though it were poisonous. We are reminded, that though the flowers of the geranium are scentless, the leaves contain a quantity of volatile oil with more or less pungent odours. A missionary in South Africa has surrounded his house with a cordon of geraniums, with the result that it is never visited by these unwelcome intruders. To the Kaffirs is attributed the discovery of this property in the geranium. It is suggested that this volatile oil might prove an antidote to snake poison.

There appears to be some probability of a tobacco monopoly being introduced at no distant date by the Russian Government, in imitation of her Western neighbour. A form of inquiry, containing twenty-nine questions on the cultivation, consumption, taxation and manufacture of the plant in various parts of the Empire, has been sent from head-quarters to the authorities in the various governments, and it probably depends on the nature of the information supplied in reply whether the State will decide to monopolize this industry for the future. The uncertainty prevailing on this point is causing some anxiety among the tobacco farmers of the south, and especially in Little Russia, Bessarabia, and some of the governments of the Volga, where the chief crops are grown. The total annual tobacco crop of Russia, including the small supplies from Siberia and the Caucasus, averages about 3,102,000 *pud*, and its money value may be estimated at 6,250,000 roubles.

Among the useful substances obtained without culture in China are various kinds of mushrooms, such as *Boletus edulis*, *Agaricus edulis*, and species of Polyporus, &c., gathered on trees, and which are employed as food, also the flowers of *Hemerocallis graminea*, which, when dried, constitutes one of the choicest delicacies of the Chinese kitchen. It is largely exported from the province of Shantung. Various tinctorial plants also grow wild, such as *Rhamnus utilis*, and *R. chlorophorus*, which yield the famous green dye of China. The bunches of flowers of *Sophora Japonica*, a tree common in the north, are collected to dye yellow. The roots of *Rubia Munjista* furnish the red madder, whilst in the south the bark of *Pterocarpus flavus* gives a yellow colour. In the north a black is obtained from the acorn cups of the oak; in the south they collect for the same purpose the gall nuts of *Rhus semialata*.

Nawab Abdool Gunny's "Agricultural Exhibition" at Dacca appears from an account published in the local paper to have been very successful as a *fête*, but a failure as an Agricultural Show.

There are 47,755 acres under tobacco in the Central Provinces, the cultivation being most confined to the Raipur district; and everywhere it is considered of an inferior quality as compared with other Indian varieties, which are largely imported. Sugarcane (98,406 acres) is also local in character, one quarter of the cultivation being in the Raipur district; Sambalpur, Betul and Bhandara having each about 10,000 acres, and there being only smaller areas elsewhere. The produce in its unclarified state is generally consumed, and it is nowhere clarified in these provinces, all refined sugar being imported from either Benares or Bombay.

Fibres (28,894 acres) are mainly of the two or three kinds of "san," the ambari (*Hibiscus cannabinus*), and the *Crotalaria juncea* being mostly raised. They are used in the manufacture of ropes and bagging, but little is exported.

COMMUNICATED AND SELECTED.

REPORT ON BAMBOO; ITS CULTIVATION AND CROPPING.

By Mr. Robert Thomson, *late Superintendent, Botanic Gardens Jamaica, West Indies.*

At your request on my return to Jamaica last spring, I continued to devote particular attention to the subject of bamboo production for paper-making, and I am glad to report with encouraging results.

While thus endeavouring to throw further light on my previous convictions, I had occasion to visit, officially, certain extensive districts of the Island in which bamboo largely abounds, and in which it is regarded as an irrepressible weed, very frequently even to the exclusion of more desirable uncultivated products.

Amongst other points of enquiry, I was anxious to ascertain the condition or degree of development in which the bamboo is best fitted for cropping to answer your purposes, and this I think I have satisfactorily settled. The point is of some interest, as much misconception (*vide* published reports) prevails as to the proper stage of growth at which the shoots may be most economically turned to account, and whereby the maximum production of those shoots adapted for paper-making is insured; hence a largely increased return from a given area as compared with the yield from crude, half-grown stems, and by the same mode of treatment the reproductive powers of the plant itself are invigorated.

My convictions under this head were formed at the time I visited Ford Works and witnessed your experiments of converting raw bamboo into "Paper Stock," coupled with the frequent discussions with you on the subject.

The condition in which the stems of this bamboo (*Bambusa vulgaris*) are fitted for cropping is readily determined by the yellowish sheaths that invest the upper portions of the stems in conjunction with the first expansion of some normal leaves which burst at the summit of the shoot. The appearance of the foliage in young, vigorous stems is immediately followed by the precipitation or shedding of these sheaths, which up to this period characterised the young stems. The average height of these shoots, at this stage of growth, after abundant rain, ranges from 30 to 40 feet, and as the apices of the shoots, to the extent of a few feet, are quite succulent, it is necessary to remove this portion.

The stems thus divested of the tops should be separated *into two, possibly three, classes of material,—i.e.*, the ligneous portion towards the base to form a distinct quality from the less indurated upper portions, which produce, as you showed me, finer and more delicate fibre, and require less active chemical treatment for their conversion into "Paper Stock."

In consequence of the unusually prolonged rainy (May) season, which this year began in June, heavy falls of rain having been experienced in the wetter districts of the Island for months, with brief intermissions of sunshine, bamboo flourished most exuberantly.

In the localities in which this gigantic grass largely abounds—*invariably in the most humid localities*—during months of August and September, an abundant stock of young shoots was for the most part ready for cropping. I traversed hundreds of acres with an equally prolific supply, which could be continuously cropped for several months in succession.

For commercial purposes, that is to utilise the stems in the condition you have found most suitable for paper-making material, bamboo has nowhere been subjected to systematic cultural treatment. Data are therefore wanting in order to test its productive power as regards the yield per acre per annum and the proportionate extent to which continuous cropping may be resorted to.

The facts which I will now relate have a direct bearing on these points, points which exemplify the ability of the plant to reproduce large and regular crops—*a view of the question not hitherto admitted by various writers.*

A few years ago, some 1,300 tons of bamboo were exported from Port Morant, Jamaica, to the United States for paper-making. All the material was obtained within a radius of a few miles; the gentleman who had the contract for supplying it for shipment received £1 per ton for the material delivered at the port. The usual price paid for felling and splitting bamboo is two shillings per cord, which, when dried, weighs about 700lbs., say about six shillings per ton, thus the cutting, crushing, pressing and carrying to the port were all performed, including the acquisition of the raw material, for £1 per ton.

The kind of bamboo that was thus utilised was *matured* stems, and they were felled *en masse* from every available clump. I was informed by the contractor that he commonly cut down clumps from the same stools twice in three years.

Also in another locality, some miles distant, hundreds of tons were prepared for shipment; in the latter locality (four years after the stems were felled) I carefully examined many of the stools from which the hundreds of tons were taken, and found the lofty and vigorous stems so completely reproduced that it was impossible to surmise that any distinction existed between them, as regards the rank luxuriance and towering height of these stems, and the surrounding groves which had not been touched.

Numerically, however, there was a material difference between the stems produced by the four-year-old shoots, and those of greater age, the oldest clumps possessing several times more stems.

Two months ago, owing to the preceding period of excessive rain-fall, as previously referred to, there was a large stock of young shoots on the clumps which had been cut down four years previously, each of the four-year-old clumps, with an average number of 40 mature stems, possessed from 8 to 10 stems suitable for paper-making material. These young stems were the result of one season's growth, and there are two seasons in the year.

The average area of each renewed clump was 576 superficial feet, say 75 clumps to the acre; each stem fit for cutting weighs fully 20 pounds.

The 40 mature stems had been produced by continuous successional sprouting, and for all practical purposes may be assumed as having grown at the rate of 10 shoots per annum during the four years.

These clumps had, of course, experienced a treatment quite different from the system which would ensure large and continuous cropping, namely—coppicing, it being understood that coppicing does not imply cutting down the *whole of the stems* or shoots to a short growth (of say two to three feet), but that such shoots only as are selected for cropping shall be cut at this height from the ground, as a certain number of stems must always be left, say one-fourth, to attain full development and to maintain the root action or vegetative functions of the plant, such stems being available at subsequent cropping for fuel.

In a previous communication, I directed attention to the advantages that would accrue from the adoption of a systematic course of cultivation and irrigation on land specially selected for the purpose. Under such circumstances there can be no doubt that the yield of shoots, as compared with the returns from uncultivated stock, would be at least doubled per annum. Thus, the precarious seasons, and the unmethodical course of procedure, implied by a chance source of supply, existing under any condition (to say nothing of irregularity of selection and extra cost of collection) would be obviated.

I was also of opinion that the St Catherine Plain, near Spanish Town, which has been rendered irrigable by the Government for agricultural purposes, would be well adapted for the establishment of bamboo plantations. On further enquiry however, it would appear that these lands are already specially reserved for other objects of culture, and consequently would be more expensive and less easily acquired than lands in most other parts of the Island.

In this connection it may be observed that rivers for irrigation purposes are available in many other parts of the Island, and if the Parish of St. Thomas was selected for the establishment of plantations, there is the advantage of procuring many hundreds of tons of young shoots annually from the existing stock, which can be cut, pressed, baled, and delivered at port, after making every allowance, for £2 per ton.

It would be a pity, however, to export the raw material in this state, inasmuch as great economy results from the conversion of it into paper-stock as you propose.

Well-managed plantations of bamboo will undoubtedly yield annual returns of young stems of from 5 to 10 tons per acre *taken as dry*, available for paper-stock.

14th November, 1878. ROBERT THOMSON.

The Madras Government will make a good thing out of their cinchona plantations. The net profit on the bark sold in 1877-8 was no less than Rs. 2,88,980. The crop taken during the year amounted to 138,808¼lbs. of which 132,951½ lbs. were shipped to England, and 5,330 lbs. were supplied to the Madras and Bombay Medical Departments. The supply of moss is becoming a source of anxiety. Several extensive private cinchona plantations have been opened out adjacent to the Government plantations, and when these estates begin to yield crop, the supply of moss will certainly fail, unless a substitute is found, or coppicing is resorted to more than hitherto. The difficulty in procuring labour is also yearly increasing.

INDIAN AGRICULTURE AND MODEL FARMS.

THERE can be but little doubt that the prevention of Indian Famines depends, in a great measure, upon the improvement of the system of agriculture pursued in the country. This system has sometimes been described, in the words of Liebig, as the "Spoliation system of agriculture." It is said that the soil is not deeply ploughed, and that there is incessant cropping without returning anything to it. Bad culture, it is argued, has an exhaustive effect on the soil. Those who hold this view, would make us believe that the increasing frequency and entireness of failure of food-crops of late years on the occurrence of drought, show that the soil throughout the country is becoming exhausted. It is not our present purpose to determine whether the soil is actually becoming exhausted or to consider the cause of that exhaustion. We, however, think that nobody will have the hardihood to deny that the method of tillage pursued by the Indian cultivator is susceptible of considerable improvement. The question is, how this improvement is to be effected? The Governor-General in Council, in defining the duties of the Famine Commission now sitting at Simla, observes :—"It is apparent that the improvement of the practical agriculture of such a population as cultivates the soil of India is a task of great difficulty. Of late years, some attempts have been made to promote this object. Their success, however, has been questionable, and measures, giving an effectual stimulus to this class of improvement, would be of the greatest value to the country."

The attempts referred to here, as having been made to promote the improvement of Indian Agriculture, are, no doubt, the establishment of Model or Experimental Farms in various parts of the country. These farms have now been in operation for some years; and we should see what results they have so far achieved. When the Imperial Department of Agriculture, Revenue, and Commerce was organised by Lord Mayo in 1871, it was said that the new Department would greatly promote the introduction of a better method of tillage by the establishment of Model Farms. These farms were to accomplish wonders. Mr. Allan Hume, who was selected to be the first Secretary to the new Department, clearly explained his views on the subject. He wrote:—

"Briefly, what I contemplate is at least one large Government Model Farm in every district of the country where all existing staples shall be grown at first in the most approved native fashion, and year by year on improved and ever-improving systems, and from seeds year by year improved by selection, and, where necessary, by interchange with other similar farms, where cattle, sheep, poultry-breeding shall be cautiously, but perseveringly, carried on, and where locally unknown staples and breeds should be gradually introduced, acclimatized, and popularized. The whole of these farms should be closely connected with each other. Their supervisors encouraged not only to vie with each other in results, but to visit and communicate with each other in the freest manner possible. Liberal prizes should be offered for those supervisors who make their farms pay best, and, besides these, provincial exhibitions should be held with the numerous prizes for excellence of produce, whether agricultural or animal, equally open to the farms and to the agricultural population generally. A special Agricultural Journal should be started for the record of all done at these farms, all experiments, all failures, all successes, so that all might know what all were doing, and so profit mutually by each other's experience."

Directly it became, on the whole, an acknowledged fact amongst the people of any district (and the people have eyes as well as we have, and can appreciate good crops and better methods of tillage just as well as we can when we *see* them) that their Model Farm was really growing better crops, or growing crops similar to their own, cheaper, or breeding better stock, or turning out better seed than they were themselves able to do; sons of well-to-do cultivators, peasant-proprietors, and the like, who concern themselves personally with practical agriculture, should be allowed and invited to reside at the farm and familiarize themselves with the system there followed, and the methods of caring for the stock there bred. All that showed capacity and intelligence, and deserved it, should be furnished at cost price, with improved seed or stock to start with on their own lands.

Each farm should, in fact, become at once a practical school of agriculture, and a source of supply of improved 'material,' whether vegetable or animal.

This was a grand scheme; and its ambitious author, Mr. Allan Hume, took care to assure the public that it was "not an Utopian idea." The project, he contended, if carried out, would even directly and fully repay its own expenses. Now, after the lapse of seven years, the public is in a position to judge of the results achieved by the Model Farms. We have no hesitation whatever in saying that these farms have proved costly failures. So far, they have not exerted the slightest influence on the improvement of native agriculture; and the reason is obvious. Lord Mayo spoke with uncommon good sense when he remarked that the establishment of Experimental Farms would be altogether useless, if attempts were made to teach native cultivators either such things as they already knew, or such improved systems of agriculture as they could not afford to practise. Mr. Allan Hume is also quite right when he says that the people of this country have eyes, and that they can appreciate good crops and better methods of tillage as well as Englishmen do, when they *see* them. The Indian cultivator may be taunted with unwillingness to depart from the ways of his fathers. He is, however, a shrewd observer and understands his interests thoroughly. The Model Farms may have shown him that better crops might be raised by the adoption of superior methods of tillage. He might have even learnt how to do likewise. But what good is the poor fellow to derive from his knowledge? He feels "that he a poor man, cannot afford to grow crops as the *Sirkar* does." For the improvement of Indian agriculture what is wanted is not knowledge of improved methods of husbandry, but capital. The ryot knows, as well as a European agriculturist, that deep ploughing and adequate manuring would lead to the production of better crops. But he cannot afford to reduce his knowledge to practice. He has no money wherewith to provide himself with improved agricultural implements and a superior class of cattle; he must burn the manurial substances, because the purchase of firewood is beyond his means. So long as *the Indian peasantry remain in their present abjectly and hopelessly poor condition, to expect any improvement in Indian agriculture,* would be to expect an impossibility. Experience has demonstrated the utter uselessness of Model Farms; they might be closed to-morrow without any injury to public interests. If the Government is really anxious to improve Indian agriculture, it should begin with rescuing the ryot from the clutches of the village-money-lender, by the establishment of Agricultural Banks, such as we have frequently advocated in these columns.—*Indian Tribune.*

SOME FACTS ABOUT LIME.

SEVERAL correspondents ask for information concerning the use of lime on land, and all of them contain evidence of several commonly accepted, but false, theories. First, lime is not plant-food; or rather it is so common in most soils, and incidentally comprises so large a portion of many fertilizers, that its application as plant-food is unnecessary. We have not seen a soil analysis from which this constituent was missing, and there is nearly always considerable of it present in available form; all true superphosphates are composed of one-fourth part or more of lime, and it is prominent in Peruvian and fish guano, in nearly or quite all manufactured fertilizers, as well as in barn-yard manure.

Lime, however, has an important effect aside from its action as plant-food. Freshly burned lime (known as "caustic lime" and "quicklime") has a strong affinity for carbonic acid, so that when it and organic matter (which always contains a large proportion of carbonic acid) are mixed together, the lime and carbonic acid unite, promoting the decomposition of the organic matter. Newly "slaked lime"—which is lime united with water—has an effect similar to quicklime, though slower, and hence is better for farm use. Fresh, undecomposed organic substances, especially dung, contain the most valuable ingredient of plant-food, nitrogen, in its simple form; but it is very soon changed into ammonia, which in turn unites at once with carbonic acid. Then when lime is brought in contact with the mass, it at once combines with the carbonic acid, and the valuable ammonia escapes and is lost. When however, the lime is applied before the ammonia is formed, the nitrogen is oxydized to nitric acid, which unites with the lime to produce nitrate of lime, and the nitrogen is saved. Therefore, lime may be used in stables and house privies, or in composting carcasses of dead animals, to advantage; but if mixed with manure a day or two old, the result is a loss of valuable material. The above also shows why, when lime is put into a compost, it has such beneficial action in hastening decomposition, and why it is necessary to use plenty of fresh earth to absorb the escaping ammonia.

Free acids, and those in easily decomposible substances, are also readily taken up by lime, and many injurious compounds, as of iron in wet lands, are rendered harmless. In some soils insoluble silicates of potash, &c., accumulate; but the action of lime will break up these combinations and set the potash free for use as plant-food.

The above statements show that the main action of lime in the soil is in making available, plant-food what was before unavailable. Therefore, while it may increase the crop-yield of poor land, it will tend to bring about its early exhaustion, unless plant-food is added. In heavy clay soils, the above mentioned chemical reaction of lime, destroy their tenacity and makes them friable and porous. Soils containing a large proportion of organic matter are benefited by its application. Wet lands are less benefited by lime than the same when drained, on account of the water. Light soils are improved by it when accompanied by a liberal application of muck or other organic matter; clays should also have the same treatment. As the best effects of lime are not apparent until the second year, it is best to apply it early in the fall; then, if the land is not rich enough, manure or other fertilizer put on the following spring will help to produce a good crop, other conditions being equal. The amount used is from 10 to 50 bushels per acre, according to the circumstances, the condition of the soil, &c.

THE SYDAPET FARM.

TO an Englishman who visited the Government Farm to witness the ploughing match ample material for ridicule, and ample opportunity for cavilling at the whole system of agricultural education were presented. If he had ever seen an English ploughing match he could hardly avoid making a mental contrast in which the dress, the manner, the implement and the performance of the competitor would form important features. The contrast would not, we fear be complimentary to the Sydapet Farm. It is not however from any wish to make the institution ridiculous, nor in any captious spirit that we desire to call attention to some of these features, not as professors of agriculture, but simply from the point of view of an outsider. On entering the field the spectator is probably pleased to see numbers of such a respectable class as that to which the student competitors apparently belong, condescending to drive a plough. It is gratifying to learn that such manual labor is not regarded by them as an indignity only fit to be performed by menial servants: but the feeling of gratification is cooled, when note is taken of the dress in which they equip themselves for their work. The English laborer and the Madras ryot alike understand how to suit their costume to their taste. Each in his way dresses himself in a manner most fitting to the circumstances, and least calculated to impede his exertions—not so the student of the Government Farm, Parsee or Hindu. Anything more ridiculous and incongruous than their costume under the circumstances can hardly be conceived. One competitor was clad in the ordinary dress of a Madras servant slippers and all. Another had boots with high heels more fitted for the pavement than the field. All, if we remember right, had on white clothing; none had either bare feet or the flat broad soled boot, which if a man is to be shod at all is the only sort of shoe in which he can move about readily over rough ground. Shod as they were, their gait was naturally unsteady, and the only wonder is that there were no dislocated ancles. We should have thought that Mr. Robertson having overcome the prejudice against labor, which is so common in this country, so far as to induce his pupils to handle a plough, might have gone a step further and persuaded them to cast aside the ornamental parts of tuari and appear in the field either in the simple costume of a ryot or in some other suitable dress. It looks as if the agricultural student, like so many other people who have given up the substance of an idea in practice, were determined to hold on to the fringe, so that they should still be distinguished as amateurs, and not confronted with the ordinary members of the ploughing class. The matter of dress serves to point an observation which we wish to make generally, with regard to the whole institution as exhibited at the ploughing match. What strikes an uninitiated observer, at least, is that the students and ryots want example more than precept: they need to see good work done in a good way with good implements. We would ask of Mr. Robertson, whether he or any of his subordinates has ever put hand to plough and practically illustrated to them, how a farm ought to be turned over. We doubt not that there has been plenty of lecturing, but we doubt much whether there has been any practical illustration. It strikes us that it would have been a useful feature in the ploughing match, if alongside of the struggling tottering students there had been a really competent ploughman, or, at least, if alongside of the waving furrows executed by them, there had been some good straight deep furrows ploughed out as a model. Nothing is more useful in all sorts of training, than to establish a good standard whereby performances can be measured. At the Government Farm there was no standard by which either spectators or labourers could guage the work done. Leaving the men, we have a few observations to make on the cattle and the implements used. Two things are perfectly clear with regard to them, that there is no comparison between the European and the native plough for efficiency, and that the former is not suited for general use in this country. For the most part the students worked with European, chiefly we believe Swedish, ploughs and of course the results they produced were far better than those produced by the native implement. But those results would not have been produced except under the favourable circumstances in which they were placed. The bullocks of the Government Farm are not fair representatives of the class bullock, they are naturally above the average in every respect, and therefore because they could draw European ploughs it does not follow that the ordinary cattle could. Clearly the ordinary pair of bullocks would succumb under the strain: but even the superior animals do not prove very efficient and certainly need a driver. Standing at a distance and not just over his cattle as with a native plough, the ploughman is at a great disadvantage, and unless he is armed with a goad, which would be difficult to wield, is completely at the mercy of his animals. As might have been seen at the match, they can stand still, turn round or go at a funeral pace, while the unfortunate ploughman is powerless. The native ploughman with his own implement is not exposed to such treatment, he commands the tails of his bullocks and little as his work is in the result, it is at least done at a decent pace. One or two men were working with hybrid ploughs which seemed efficient enough, and not so open to the objection of weight: but even of them it might be objected that they threw the ploughman too far back from his bullocks and therefore necessitated the presence of a driver. Of course too they are too heavy to be carried about with the facility with which the plough of the country is carried. Altogether we fear very much, that there will be no real improvement in agriculture until there is material improvement in the draught cattle. The saddle must be fitted to the wearers' back, and it is useless introducing English or Swedish implements, before animals are forthcoming which can draw them. If the Government Farm is to be efficient for good, it is we think by way of example: if the Hindu is to be dragged out of the groove in which he works and which probably dates from a time anterior to the infusion of the Aryan race, it must be done by showing him demonstratively, that better results may be produced by better means. Example, is what rather appears to be wanting at this institution; we cannot believe that we should have seen the incongruous costumes which we saw at the match, if Mr. Robertson's European subordinates were sometimes in the habit of descending into the arena, and showing in their own persons how good work ought to be done.—*Madras Athenæum.*

CARBON AS PLANT FOOD.

THE great mass of vegetable matter is composed of woody fibre (cellulose), which consists of carbon 44 per cent., oxygen 49·62 per cent., and hydrogen 6·38 per cent. Nearly one-half of the vegetable growth of our forests and fields is, therefore, organised carbon. This substance is known to us in the form of charcoal, though the diamond is pure crystallized carbon. In its uncombined form, it is not soluble in any known liquid, nor is it fusible in any heat we have been able to produce. At red heat, it combines readily with oxygen in a brisk combustion, without flame, and the product is a gas composed of 27 per cent. of carbon and 73 per cent. of oxygen, and commonly known as carbonic acid. It has a feeble acid reaction, and forms salts with alkalies. At the temperature of 60 degrees, water will dissolve and hold in solution its own measure of carbonic acid gas; but it parts with it all at a boiling heat. In this form all the carbon appropriated by plants is furnished, and it would be a very natural inference that to furnish a supply of carbonic acid would be the first care of the farmer. But this would be altogether an erroneous conclusion.

From various sources, the air is always supplied with carbonic acid in sufficient quantities to answer the demands of plant growth; but the chief interest of the farmer is to place his crops in a favourable condition to appropriate the carbon brought within its reach. An animated dispute has been carried on for several years between two schools of vegetable physiologists—the one contending that all the carbonic acid used by the plant was absorbed by the leaves, and the other holding that a portion of it was supplied by the roots, being held in solution in the water absorbed. The question, however, is one of but little practical importance, as both parties admit that plants derive all their carbon from carbonic acid, and that the decomposition of that gas takes place in the leaf.

The important matter, practically, is to understand the conditions under which vegetables appropriate carbonic acid; for this is the secret of their growth. Those conditions are chiefly two: first a healthy condition of the leaf; second, a full exposure to sunlight. The first of these is that which chiefly concerns us. Leaves absorb carbonic acid in proportion to the amount of green colouring matter they contain. This, as I have always said, depends on a supply of nitrogen in a form that the plant can use it.

Ammonia dissolved in water and absorbed by the roots is the usual form in which the supply of nitrogen is obtained. This is decomposed in the leaf by the agency of sunlight, and the nitrogen, set free, immediately enters into a new combination, and the green colouring matter is the result. But this change demands the presence of potash and phosphoric acid; in very minute quantities, indeed, but still essential. A deficiency in any one of these conditions will give a pale or yellow leaf; and every farmer knows what that means, though he may not be able to explain why it is so. But plants absorb no food, by the leaf, in the dark, and there is no chemical action in the absence of sunlight. It is true that plants grow at night; but they grow by using the material prepared in the light and by its agency.—*R. T. Brown, in the Country Gentleman's Magazine.*

THE NELAMBUR TEAK PLANTATIONS.

MANY of our readers are probably unaware that the Government possess at Nelambur, a station on the Western Coast, some forty miles inland from Calicut, a most valuable property in the shape of teak plantations. We are not in a position to write a full history of these rich plantations, but we have been enabled to gather together a few items of information that may not perhaps prove uninteresting. At any rate we think they will clearly prove that the Government has made an excellent investment in creating them, while the public is greatly benefitted by being allowed to purchase the timber produced there. We all have heard of the success of the cinchona speculation which the Government is conducting on the Neilgherries, but of the older undertaking—the teak plantations —we hear but little, although they are in our opinion almost of as vast an importance as the first mentioned. We believe the original motive for their establishment was ultimately to secure a regular supply of good teak timber for the use of the East India Company's Dockyard at Bombay; but since the time they were started, not only has the dockyard establishment dwindled to very small proportions, but the old Company itself has disappeared. The existing Government, however, are reaping the benefit of the wise forethought displayed by those who first advocated the creation of these forests, and it is not too much to say that they were indeed public benefactors. We believe they were first commenced about forty years ago under the auspices of the late Mr. Conolly, the Collector of Malabar, who was murdered by some Moplahs. It may be remembered by our older readers that the murder of the gentleman named was the immediate cause of the passing of the Moplah Act, the stringent measures provided by it having been put into force on several occasions, and so recently, if we recollect rightly, as last year. Dr. Cleghorn when chief Conservator of Forests for Madras took lively interest in the experiment, and we believe it was at his suggestion that the gentleman, who has been in charge of the plantations since 1862 was brought out to the country. This gentleman has met with but scant courtesy at the hands of Government, if judged by the success which has attended his labours and the small pay he still receives. The success which has attended the enterprise is due in a very great measure to his constant and arduous labours, and we trust he will shortly receive his due reward. The plantations at present cover an area of three thousand four hundred acres, and have cost for supervision and working charges from the year 1840 to March 1877 nearly two and a half lakhs of rupees. Of this amount, however, one lakh and twenty-four thousand rupees have been recovered by the sale of thinnings, so that the balance at present standing to the debit of the plantations is about one lakh and sixteen thousand rupees. The prospective value it is somewhat difficult to calculate and we must turn to the rate of growth to enable us to arrive at a fair estimate.—*Madras Athenæum.*

IN accordance with the instructions of Government the Conservator of Forests visited the Government teak plantations in Malabar last year, and submits full details as to their extent, cost and present condition, with his views as to their future financial prospects. Colonel Beddome's inspection was very thorough, and his scrutiny of the past and probable expenditure and receipts very searching and complete; but the result is that he anticipates "an enormous yield and very large profits." This report is specially satisfactory as hitherto he has not been sanguine as to the success of the enterprise.

The Nelambur Forest Division is divided into fifteen blocks, and, according to survey measurements, their acreage is as follows:—

				Acres.
Planted	...	...	...	... 3,435·98
Unplanted	...	...	...	... 15,433·71
			Total	... 18,869·69

The planted portion is further divided according to its anticipated yield as based on its present condition:—

				Acres.
E.G.				
Full yield	...	...	...	... 1,787·85
4/5ths	...	...	...	... 825·75
3/5ths	...	...	...	... 539·26
2/5ths	...	...	...	... 273·78
Nil	...	...	...	... 509·84
			Total	... 3,435·98

Thus on "509 acres or more than 1/7th of the whole" planted portion the growth is so poor that the Conservator thinks it safest to enter the anticipated yield as *Nil*, though he considers "there is much that might be classed as 1/5th."

The following abstract statement exhibits the charges and receipts for the whole division from 1840 to 1877-78:—

Charges.	Rs.	A.	P.	Receipts.	Rs.	A.	P.
Acquisition of land, &c..	1,00,840	7	4	Timber	1,57,798	7	2
Establishment	1,47,635	1	11	Bamboos	10,755	0	8
Charges on timber	45,114	12	6	Saplings	1,29,312	13	6
Plantation charges	1,51,896	14	6	Miscellaneous	2,535	13	1
Floating operations	31,008	3	2				
Total	4,77,395	5	11	Total	3,00,402	11	5

The Board of Revenue, having supplemented the Conservator's figures with details furnished by the Collector, calculate the total debt of the plantations, "accumulated at 4 per cent. compound interest, at Rs. 3,77,827."

To estimate the future return from the plantation it is necessary to determine the age at which the trees will arrive at maturity, the number and cubical contents per acre, and the price the timber will fetch.

Colonel Beddome believes that the trees in the plantations will grow and develope more rapidly than those in the natural forests, and as those are found to be mature at about sixty years, this may safely be taken as the age of maturity.

For the first thirty years of their life the upward growth of the trees is encouraged, but as the numbers originally planted become much thinned out, and air and light are admitted, and there is more space, this tendency is somewhat checked, and the growth in girth takes its place. Some of the trees in the older plantations already contain 100 cubic feet of timber, so that this amount may safely be taken as the average cubical contents of the trees of which sixty per acre are to be left to mature.

As the first regular felling of mature timber cannot take place until the year 1904, it is impossible to estimate the prices that will then prevail. The market depôt will be at Calicut, to which the timber can be transported from the plantations at a cost of 3 to 5 annas a cubic feet. The prices now range at that place from Rs. 1-8-0 to Rs. 2 per cubic feet, so that the Conservator's estimate of a net profit of 10 annas per cubic foot is exceedingly moderate.

From the foregoing data it is assumed that from the 2,484¼ acres which are expected to yield a full crop, 14,906,108 cubic feet of timber will be harvested, realizing Rs. 90,00,000.

It is stated that teak trees may be allowed to stand for fifty years after maturity, and that thus felling on the existing plantations need not close until the year 1986, and will thus be spread over a period of eighty-two years. This makes the average yearly profit Rs. 1,14,375, and the Board calculate that this sum, accumulated until the above date with interest at 4 per cent., will amount to Rs. 684,26,780 against a debt of Rs. 261,14,960 similarly calculated.

Colonel Beddome concludes his report with discussing the question of the extension of planting operations. Land is available, though much of this for different reasons he considers it inadvisable to plant. He would not, it seems, enlarge the planted area until the year 1900, though he would apparently commence to raise a second crop on some of the land already occupied when the trees on it are reduced to their final number of sixty per acre.

The Board of Revenue point out that it will not be necessary as far as the timber is concerned to spread felling over so long a period as eighty-two years, and that if it is to be carried out more expeditiously it may be advisable to undertake further planting.

The question is one of difficulty, and further discussion is in the opinion of Government necessary to its decision. At present the Conservator states there would not be a market at Calicut for an annual harvest of teak of the extent expected, and some experience as to the quality of the timber seems necessary.

KANS GRASS IN BUNDELKHAND.

Extract paras. 1 *and* 2 *of Allahabad Commissioner's No.* 803, *dated* 31*st August*, 1878.

I HAVE the honour to enclose a letter in original from the Settlement Officer of Banda, No. 329, dated 24th instant, with enclosures, containing an interesting report from Mr. E. C. Schrottky, giving the results of his analysis of certain specimens of *már* Bundelkhand soils selected with reference to the growth of káns grass.

2. Mr. Cadell, I think, conclusively shows that the analysis made of the káns-growing soils is incomplete, and that it is desirable to have similar analysis made of the káns-growing soils of *kábar* and *parua*; I therefore recommend that sanction be given to the analysis of these soils, and that a further expenditure of (say) Rs. 800 may be sanctioned for this purpose.

Extract paras. 1 *to* 3, 5 *and* 6, *of Banda Settlement Officer's No.* 329, *dated* 24*th August*, 1878.

I have the honour to enclose a report by Mr. E. C. Schrottky, on káns grass in már, and to solicit your instructions on two points connected with it.

2. When your predecessor was in Bánda last August, I spoke to him regarding the analysis of Bundelkhand soils, and he agreed with me that it was desirable to have analysis made. I accordingly entered into correspondence with Mr. Schröttky, and at first intended to have a fuller investigation made than was eventually undertaken. But I was restrained partly by the expense, and partly by Mr. Plowden telling me that the Geological Survey Department was about to make analysis of our soils.

3. I accordingly asked Mr. Schrottky to restrict his analysis to three specimens of soils, *all már* :—

(i.)—Soil not affected by káns within the memory of man.

(ii.)—Soil under káns and uncultivated.

(iii.)—Soil recently under káns but now again brought under cultivation.

5. As to the report itself, I think the results obtained by Mr. Schrottky must be held to be inconclusive, as the investigation has not extended to kábar and parua. Mr. Schrottky, following the statement of Mr. Court, that káns grows only in már and kábar, and overlooking, I think, my contradiction of that statement, assumes that kans is unknown in parua, whereas it is frequently met with in that soil, and is more prevalent in kábar than in any other soil. Until, therefore, a similar analysis is undertaken with reference to kábar and parua, the investigation cannot, I think, be held to be complete, or the conclusions based on the investigation trustworthy.

6. From his analysis of Mawai már Mr. Schrottky comes to the conclusion that the growth of káns is owing to the superabundance of lime and silica, and to the deficiency of potash and phosphoric acid.

But there is már (see No. 2 in the Geological Survey Assays) in which there is but little lime ; and in the kábar specimens (9,) taken from the most káns-grown neighbourhood, there is very little, while in No. 12, patli rákar, there is more lime than in any other soil. These assays do not give the proportion of silica, but the deficiency of lime in kábar and parua is enough to suggest that assumptions based on the már of Mawai alone are very probably insufficiently supported. So far from Mawai being a fair representative of all Bundelkhand soils, it is not a sufficient representative of Bundelkhand már ; and, interesting as Mr. Schrottky's report is, more and more widely selected instances are required to justify the conclusions at which he arrives.

The only other analysis of Bundelkhand soils of which I know are those extracted from Medlicott's Cotton Hand-book, in pages 48 and 49 of Mr. White's report on pargana Kalpi, and those made by Dr. Murray Thomson for the Betwa Canal Project, given in the same report.

Those analyses, if they show nothing else, show that the extraordinary differences between different specimens of soils of the same class given in the Geological Survey Assays have been observed before, and those of Dr. Murray Thomson, that in már the percentage of lime is sometimes less than in ordinary loam.

For my own part, I have never been very hopeful that chemical investigation will lead to the discovery of any practical remedy for káns. The weed seems to be always ready to spring up, and its presence, is, so far as can be seen, accounted for satisfactorily in very different ways in different villages and tracts.

But it seems to me to be none the less desirable that the chemical aspects of the question should be thoroughly investigated.

If there is a practicable remedy it should be ascertained. If, on the other hand, chemistry cannot help us, it is well that we should be assured of the fact.

The successful administration of Bundelkhand is a problem of sufficient importance to justify the expenditure of a few hundred rupees upon an investigation which, if it does not supply a remedy for a very serious evil may at least put an end to these doubts and questions which periodically arise and divert attention from what, I am afraid, is the only remedy for the ills to which Bundelkhand is liable— that improved revenue administration which shall render the people more prosperous than they have ordinarily been during the seventy-five years of our administration, and therefore more able to contend with the difficulties in their way.

No 5, Middleton Street, Calcutta, 20th June, 1878.

THE SPREAD OF KANS; ITS CAUSES AND REMEDIES, WITH ANALYSIS OF SOILS AND PLANT.

To—A. CADELL, ESQ., C.S., *Settlement Officer, Banda, N.-W. P.*

SIR,—Referring to your letters dated 19th January and 13th March, 1878, requesting me to analyse several samples of soil from fields in the Banda pargana infested with káns (a weed very prevalent in Bundelkhand), and likewise sample of soils from fields on which káns never appears, with the object to ascertain whether chemical analysis of the different soils can throw any light on the cause or causes to which the appearance and disappearance of káns is due, I have now the honour to hand you my following report and the results of my analysis.

I confined myself to the analysis of (1) a sample of soil infested and overgrown with káns, (2) a sample of soil recently grown with káns, (3) a sample of soil on which kans never appears, and (4) the ashes of the plant itself.

As the subject appears to be of considerable importance, it will not be out of place if I preface my report by a *résumé* of what is known about káns. The remarks in brackets are mine : the rest is condensed and based upon information derived from Mr. Mayne's and Mr. Court's reports on the subject published in the Revenue Reporter, North-Western Provinces, New Series Vol. III, No. I, and from the rent-rate report of pargana Maunha of the Hamirpur district.

Káns is a weed very prevalent in Bundelkhand, Rohilkhand, and the Doab, but, on account of the peculiar nature of the soil, is most destructive in the first named district.

Its botanical name or classification seems to be unknown ; it is called a grass [and looks very much like one]. Mr. Edgeworth describes it as *Saccharum spontaneum* ; but then, again, Mr. Court states that it produces a white flower [and therefore it cannot well be a *Saccharum* nor can it belong to the *Graminaciai*]. The plants sent to me were without flower, and I could not therefore positively determine to what family of plants this weed belongs.

I would recommend a flowering specimen to be sent to the Curator of the Calcutta Botanical Gardens for classification, as likely to throw some further light on the subject.

Káns is a perennial weed, springing first from seed, but spreading afterwards chiefly by the roots forming a regular and thick network, which effectually chokes every other plant and stops completely all cultivation. If káns is once permitted to take hold of a field it is almost impossible to eradicate it by any ordinary plough, as the roots strike downwards to a depth of eight or ten feet and are very thick and strong.

The plant itself is some four or five feet high, and its stems and shoots so hard and thick that a man or horse can only with difficulty walk through it.

Káns is peculiar to certain soils, chiefly kábar, már, or the wet már soil representing varieties of a heavy tenacious clay, full of kankar or lime in small pieces ; it never appears in light soils, nor in virgin soils, nor in well-manured or naturally rich clay soils.

It has never been known to take root in these soils [though its seed undoubtedly must have had access to it, but failed to germinate on account it may be surmised, of the absence of some peculiar condition of the soils essential for its development].

If káns has taken possession of any field and is left alone, it exhausts itself after ten to fifteen years' continuous growth [or rather, as I would prefer putting it, exhausts in that period the peculiar elements in the soil which support it]. If, however, the soil is disturbed or cultivated, káns will last longer [that is to say, when atmospheric climatic influences are allowed to act upon the soil by stirring it up, and sets free from chemical combination some more of the peculiar elements káns is partial to ; the additional nourishment thus furnished will prolong the existence of káns beyond the usual period.]

So soon as káns has exhausted the land, after its ten to fifteen years' continuous growth, it dies out, and the land is again fit for the cultivation of agricultural produce.

Káns never makes its appearance again in the same soil for eight to ten years [during which time it can rationally be assumed the action of moisture, heat, and atmospheric air upon the cultivated—that is to say continuously stirred—soil sets free sufficient of the peculiar element or elements essential to the growth of káns. Káns seed will then again germinate in such soils, and unless at once checked, the land must be again abandoned and given up to the growth of káns for a similar period.

There are, it is stated, some old men who have seen káns appear and disappear two or three times within their own memory.

[These peculiar circumstances under which káns appears and disappears give a great scientific interest to the subject of this enquiry, and must be my excuse if I dwell at some length on some points which to many persons will appear at first sight as irrelevant to the main question at issue.]

The only effective means known at present to prevent káns from taking possession of any land favourable to its development is to turn up the young weed year by year by frequent ploughing, and to sow for crops as usual. This requires of course strong ploughs and bullocks, and the fields must be continually and carefully attended to, for if once the roots of this weed get below the depth of the plough, all endeavours, within the reach of the ordinary ryot, to eradicate it are futile, and the land has to be abandoned for ten or fifteen years.

Overcropping is said to be one great cause of the appearance of káns, but beyond this nothing is suggested which could give a clue to the discovery of the real direct cause to which the appearance of this injurious weed is due.

It is universally admitted that at certain intervals the soil is more predisposed to grow káns than at others, and large tracts—nay, whole villages—have to be abandoned and thrown out of cultivation on account of it if at any time unfavourable seasons impoverish the ryot, reduce the number of his ploughs and bullocks, and thus disable him to give the land the extra cultivation required to keep down the weed at first appearance.

Passing now from these general remarks on what is known about this reed, and what can be deduced from it, to the results of my analyses which are appended, we find on comparing the different items of analyses of soils, No. I [never affected with káns], soil No. II. [overgrown with káns], and of soil No. III [recently grown with káns], first a large excess of organic matter in No. II soil, occasioned undoubtedly by the accumulation of roots and stalks of káns in the soil. Potash and soda as well as phosphoric acid [all three important elements of mineral plant food] are present in much smaller quantities in Nos. II. and III than in No. I soil, and the two first must, therefore, be classed as much poorer soils, giving support to the observation that káns will never grow on virgin or well-manured lands, and that injudicious exhaustion of the soil is one of the causes of its appearance

There is some additional potash and phosphoric acid present in these soils, but in such powerful combinations as to be insoluble in hydrochloric acid. This quantity as usual has not been separately estimated, but is included under clay.

The difference of the quantity of the oxide of iron and alumina between the three specimens of soils can be disregarded as not affecting plant life to any extent.

But the chief difference between these soils, which throws some light upon the cause why káns will not grow in No. I soil, while it flourishes in Nos. II and III, is evidently the proportion of lime and soluble silica.

The amount of lime in No. II and No. III soils exceeds that of No. I by 50 and 68 per cent respectively, and, likewise, the amount of soluble silica in No. II and No. III exceeds that of No. I by 128 and 156 per cent. respectively.

Judging, therefore, from the chemical composition of these soils, it would appear as if a certain excess of lime and soluble silica, and poverty of the soil in potash, soda, and phosphoric acid, were essential to the development of káns.

But, while giving due weight to the results of the ordinary chemical analysis of these soils, it must be borne in mind that such an analysis shows us, indeed, what the soil consists of, and how much of each element of mineral plant food, soluble in hydrochloric acid, is present; but it does not reveal to us how much of each of these elements is available to the plant.

The mineral plant food in arable soil, such as potash, soda, lime, and magnesia, sulphuric, phosphoric acid, and silica, is present in two different states of combination, *viz.*, in physical combination with the soil and in water in insoluble chemical combinations with each other.

To make this point clear, a piece of granite I lately analysed consisted of silica 72·65, oxide of iron 7·1, alumina 8·95, lime 2·82, magnesia and alkalies 5·2, phosphoric and sulphuric acid 0·28, water of combination and loss the remainder.

All the elements of mineral plant food are there; but if we were to powder this piece of granite and try to grow any plant in the powder, we would fail in our experiment, as the plant cannot absorb a particle of the plant food which is present, it being in chemical combinations insoluble in water.

In course of time the constant action of moisture, heat, and atmospheric air severs these chemical combinations; the granite powder will become gradually decomposed, the different elements of mineral plant food are set free, become soluble in water or in water containing carbonic acid and are then available and can be absorbed by the plant.

Precisely the same process takes place continually in the arable soil of our fields, with the difference that as the different elements of mineral plant food are set free from their chemical combinations and become soluble in water pure and simple, or in water containing carbonic acid they immediately enter into a kind of physical surface combination with the porous particles of the arable soil which prevents them from being washed away and removed from the surface soil by rain and drainage.

If water containing in solution a certain quantity of potash, soda, lime, phosphoric acid, silica, &c., is allowed to percolate through a stratum of arable soil, a certain quantity of these substances will be retained by it, entering with it into a physical surface combination; and the soil will continue to abstract such soluble mineral plant food until its affinity for it is satisfied and saturation takes place; after this, all soluble mineral plant food passes through without any absorption taking place.

Now the physical affinity of the soil for mineral plant food in a state of solution in water is greatest for potash and phosphoric acid, the two scarcest and most important elements of mineral plant food, while its affinity for lime and silica is smallest, these being, so to speak, the commoner elements and generally present in abundance. Deep well water, therefore, always contains them, the soil permitting them to pass through unabsorbed.

Now, the rootlets of plants come in contact with and press against the particles of the soil which are enveloped by the mineral plant food that entered into physical surface combination with them; a constant change is going on between the cells of the rootlets and the moisture without; osmose and exosmose come into play, which, combined with the vital power of the plant, overcomes the affinity the soil possesses for soluble mineral plant food; the latter becomes again soluble in water, and is thus absorbed by the plant.

We speak, therefore, of *available* and *unavailable* mineral plant food in the soil—the former once soluble in water, but bound by the physical affinity of the soil; the latter still in insoluble chemical combinations with each other, and, while thus, unfit for plant food until by the action of moisture, heat, and atmospheric air these combinations are severed.

It follows, therefore, that we have reasons to believe that germination and the development of any particular plant is dependent upon a certain excess of lime and silica, this excess must consist of *available* lime and silica. If by ordinary chemical analysis we find that a soil in which káns never grows contains 6·5 per cent. of lime and 3·2 per cent. of soluble silica, and another soil peculiarly favourable to the development of káns and overgrown with it is found to contain 10·6 per cent. of lime and 7·32 per cent. of soluble silica, we may reasonably suspect that this excess of lime and silica has something to do with the presence of káns; but we cannot speak positively until we know how much of this lime and silica is available as food and influences the plant.

Now, agricultural chemistry has not yet discovered any acid or solving medium which exactly corresponds in dissolving power to the force of osmose and exosmose combined with vegetable vitality; it is practically unable to ascertain how much available mineral plant food there is in any particular soil, or how much of each constituent.

Ordinary chemical analysis cannot distinguish between powdered granite and arable soil, and it is therefore, extremely hazardous to judge of a soil and report on its peculiarities simply on the basis of an ordinary chemical analysis.

I have gone into great length in explaining the difference between available and unavailable plant food, as it has important bearings upon the subject submitted to me for report; for on the basis of the results of the experiments detailed below, I have come to the conclusion that *an oversaturation of the soil with available lime and silica, and notably the latter, is essential and necessary for the germination and development of káns.*

I percolated 1,000 grains each of soils Nos. I, II and III with very diluted [1 in 100] acetic acid containing half per cent. of hydrochloric acid and 2 per cent. of carbonic acid [the last by volume]. Having found after many experiments that this mixture has very little effect upon mineral plant food in chemical combination, while it dissolves nearly all available plant food, I do not claim this mixture to be the exact equivalent of the force of osmose and exosmose combined with vegetable vitality, but I have every reason to believe that the results are approximately correct and sufficiently, so far as general conclusions.

The ordinary chemical analysis having given me the clue, I only estimated lime and magnesia.

Forty ounces of the above described liquid containing acetic, hydrochloric, and carbonic acid, were percolated through a thousand grains of each of the soils and dissolved out of—

	Soil No. I.	Soil No. II.	Soil No. III.
	Grains.	Grains.	Grains.
Lime	12·2	30·3	28·5
Silica	4·1	12·6	11·9

I further percolated 10,000 grains of each of these soils with two pints of distilled water, and found it abstracted from—

	Soil No. I.	Soil No. II.	Soil No. III.
	Grains.	Grains.	Grains.
Lime	0·6	10·3	11·2
Silica	0·12	2·4	2·3

The results of these two experiments lead to the conclusion that there exists a distinct peculiarity in soils No. II and No. III, this peculiarity consisting of an oversaturation with available lime and silica; and this peculiarity not being shared by soil No. I points to such oversaturation as an essential and necessary condition for the development of káns.

This excess of lime and silica in soils No. II. and No. III is, however accompanied, as analysis shows, by great poverty in potash and phosphoric acid, two most important elements of mineral plant food for the majority of our agricultural produce; hence it can be rationally concluded that if these soils were oversaturated as well with potash, phosphoric acid, &c., káns would not be able to exist in them.

To favour, therefore, the development of káns, the oversaturation of the soil with available lime and silica must be accompanied by a corresponding want of available potash and phosphoric acid.

The analysis of the ashes of káns shows that it is an essentially siliceous plant, silica and lime being the chief constituents, the ashes containing—of the former 75·5, of the latter 9·3 per cent. The specific character of the plant would have come out sharper under analysis if the *flowering* plant food would have been sent to me, as only at that period the plant contains all the elements of mineral plant food in the proportions essential to its development and propagation, and the safest deductions can be made from an analysis of the plant at that stage of existence.

To sum up, káns is a siliceous plant, flourishing in soils which contain an excess of available lime and silica, notably the latter, and are at the same time poor in available potash and phosphoric acid.

It will develop in such soil to an extent precluding all cultivation, and its principal mineral food being lime and silica, will take up yearly a considerable quantity of these two substances in their available state, and fix them in insoluble combinations within its cells. If the decomposing action of moisture, heat, and atmospheric air is reduced to a minimum by not stirring up the soil, then very little lime and silica will be set free to and to the excess already existing; and under these circumstances the continuous growth of káns will absorb every year a certain proportion of this excess of lime and silica and exhaust it, as observation has shown at the end of ten to fifteen years, sooner or later, according to the nature of the soil.

As soon as this excess is exhausted, the condition essential to the development of káns has ceased to exist, the weed dies out, and the land is again fit for cultivation.

If, however, the land occupied by káns is stirred up, more lime and silica is rendered available from their chemical combinations, and the period during which káns exhausts the excess of these two elements of plant food will be prolonged.

As said before, after káns has died out, the land can again be cultivated for the ordinary crops. Cultivation exposes all particles of the surface soil to the decomposing action of climatic influences; lime, silica, potash, phosphoric acid, &c., are set free, and rendered available to vegetable plant life. The land being either altogether poor in potash and phosphoric acid, or containing these elements in powerful chemical combinations not so easily decomposed as the lime and silica combinations, preponderating

quantities of the latter two elements, largely in excess of what the ordinary crops can absorb, will be rendered available.

These quantities being accumulations, the soil will, after a certain number of years, contain such an excess of lime and silica as to make it fit again for the growth of kâns.

What will be the number of years—said to vary between six and eight—will depend entirely upon what crops are grown on it.

If wheat or other siliceous plants are grown, which in addition to potash, phosphoric acid, &c., abstract likewise a considerable quantity of the silica set free year by year, then a greater interval will elapse before the land becomes again fit for kâns; but if non-siliceous plants, such as juár, gram, &c., are raised, which require for their growth large quantities of potash and phosphoric acid, but very small quantities of silica, then the land will become sooner fit for kâns. Mr. Mayne's statement, that some people say "that kâns follows juár with greater force," adds considerable weight to the above abstract deduction.

The direct causes, to which the appearance and disappearance of kâns is due is once recognised, the remedies are simple enough and should prove efficient.

I know nothing of the lay of the land on which kâns grows; but if there was a good natural subsoil drainage, experiments have shown conclusively that no oversaturation of the soil with available lime and silica can take place. The soil possesses but feeble physical affinity for these two elements of mineral plant food, while its affinity for potash and phosphoric acid is very great; and if there was a good natural subsoil drainage, any excess of lime and silica would be at once removed from the upper cultivated stratum.

I would recommend, therefore, as a remedy against kâns, to drain the soil by drains 4 to 5 feet deep, 2 feet wide, and 30 to 50 feet apart, and either leave them open and then with embankments, so as to prevent surface drainage, or cover them up with soil after having previously half filled them loosely with stones or brushwood.

All these drains must of course incline to the open drainage of the country. The soil must be loosened so as to enable rain or irrigation water to run through it, not over it. It may either be hoed, or, if the great strength of the roots of kâns make that impracticable, it should be straight-holed, six or nine inches deep and six or eight inches apart, with a crowbar or similar straight implement.

It is not necessary to dig up the kâns, that will die of its own accord as soon as subsoil drainage actively sets in and removes the excess of available lime and silica.

This operation should be aided by spreading over the soil newly-burnt and slaked lime at the rate of one to 1½ ton per acre.

Any kind of kankar or limestone can be burnt for the purpose. After spreading the caustic lime over the soil, it should be lightly dug into it. The greatest effect will be obtained if the land has a good natural or artificial watering immediately the lime is dug in.

Lands thus treated will give double and treble the average yield for a number of years, and this will amply cover the extra expenditure of reclaiming them from kâns.

It may appear strange to recommend the addition of lime to a soil which is already too rich in it, but in this case it is not used as a *manure* in the narrow meaning of the word, but it is used on account of its powerful chemical action in its caustic state. Caustic lime will burn up the kâns; decompose rapidly, and to the benefit of succeeding crops, the excess of organic matter accumulated in the soil by the continuous growth of the weed; it will set free from their chemical combinations potash and phosphoric acid, which are greatly wanted in these soils, and combine with the available silica to an insoluble silicate of lime; while any excess of lime will be removed by subsoil drainage.

I remember an instance which came under my personal observation of a field in Germany being for years covered with the common scouring rush (*equisetum*) to such an extent that *equisetum* seemed to be the crop, and rye, which was grown on the field, an adventitious weed.

Equisetum, I may mention, is also a weed requiring large quantities of available silica for its sustenance, its ashes (*Equisetum hyemale*) having been found to contain no less than 97·5 per cent. of silica. I saw this field subsoil-drained, and the *equisetum* disappeared totally, as if by a miracle, within one year.

Appended are the results of my analysis of the three soils and of the ashes of kâns.

I have, &c.,
(Sd.) EUGENE C. SCHROTTKY.

RESULTS OF ANALYSIS OF SOILS FROM MAUZA MAWAI BUZURG, PARGANA BANDA.

(Soil No. I, a rich clayey soil No. II, calcareous clay soil, poor in potash and phosphoric acid, subsoil consisting of clay and kankar; soil No. III, same class of soil and subsoil as No. II. No subsoil was sent of No. I).

100 GRAINS CONTAIN OF	No. I. Field No. 434, never affected with kâns.	No. II. Field No. 410, not cultivated and is overgrown with kâns.	No. III. Field No. 438, recently grown with kâns.
Organic matter and water of combination	4·50	8·19	6·50
Potash and soda as chlorates and sulphates	1·28	0·36	0·83
Lime carbonate	0·50	10·6[illegible]	9·09
Magnesia do.	0·80	0·80	0·50
Phosphoric acid	0·28	0·1[illegible]	0·15
Oxide of iron and alumina ..	6·18	8·30	10·20

RESULTS OF ANALYSIS OF THE ASHES OF KANS (THE WEED NOT BEING IN FLOWER).

The whole plant was carefully incinerated.

100 grains of the ashes contained—

Potash and soda	4·6
Lime	9·3
Magnesia	3·2
Chlorine	0·3
Sulphuric acid	0·8
Phosphoric acid	2·1
Oxide of iron and alumina	4·2
Silica	75·5
	100·0

(Sd.) EUGENE C. SCHROTTKY.

NEW COMMERCIAL PLANTS.

MR. THOMAS CHRISTY, F. L. S., is indefatigable in bringing these to public notice. In pamphlet No. 2, he gives an account of *Gynocardia Odorata*, the Chaulmugra tree, the seeds of which yield an oil (Chaulmugra oil), which has long been known and valued in India for the cure of leprosy and allied diseases. We are told that :—

Chaulmugra Oil is now being used in St. Peter's Hospital, Berners Street; the Infirmary at Margate; in the Royal Hospital for diseases of the chest, City Road; in St. John's Hospital, Leicester Square, and other Hospitals, and by several leading members of the medical profession in London.

Next we have an account of Vogel's African rubber tree, *Urostigma vogelii miq.*, of which we are told :—

The tree will grow near the sea at an elevation of 50 to 60 feet above sea level, but does not flourish well in marshy ground.

The ease with which the plant is propagated, its hardiness in sea air, and the excellent quality of the rubber which it yields, render this a desirable species for cultivation in the lowlands of southern India and Ceylon; also in Java, Sumatra, Penang and Siam.

The mahwah tree (*Bassia Latifolia, Roxb.*) forms the subject of the next article. From time immemorial, an intoxicating drink has been made in India from the flowers of this tree. More interesting is it to know that the sugar which leads to fermentation makes the flowers valuable for food. Listen :—

The flowers are produced in enormous quantities in March and April, after the old leaves have fallen and before the new leaves have appeared; the crop rarely fails. The fleshy flowers fall off and cover the ground beneath the trees, and are gathered eagerly by the natives every morning during the flowering season; a single tree yields from 200 to 400 lbs. weight of flowers. These flowers are stored as a staple article of food by the Bheels and other tribes, and so valuable do they consider these trees, that in time of war the threat of cutting them down generally reduces them to submission when unruly.

The flowers when dried have somewhat the odour and appearance of Sultana raisins. Lately examined by a French chemist, M. Petit, they were found to contain half their weight of sugar, and are therefore very nourishing.

In a paper recently read before the Linnæan Society by Mr. Lockwood, that gentleman stated that wild animals of many kinds troop eagerly to the mahwah trees during the season to feed on the flowers. He was therefore led to experiment upon domestic animals, and it was found that the flesh of pigs fed upon mahwah flowers in this country was much improved and acquired a delicate flavour. The animals so fed rapidly came into condition. Again :—

The tree thrives in poor stony ground, and might therefore be cultivated on land not available for other crops. So regular is the yield of flowers, that it is said a bad mahwah harvest has never been known in India. The flowers when dried will keep for almost any length of time, and do not appear to be attacked by insects.

From the seeds an oil is extracted by the natives; it is used for lighting purposes and for soap-making. The smoke arising from the burning of the oil-cake, after expression of the oil, is said to be poisonous to rats, &c.

The mahwah tree, then, affords a means of obtaining an almost unlimited supply of food, both for man and beast, a food which will keep a great length of time in any natural temperature, and which requires no trouble to procure, and no outlay in cultivation. The tree readily propagates itself by seed which, in India, is usually self-sown.

As of special local interest we quote in full the notice of cacao :—

Theobroma Cacao.

It is not generally known that the flavour of cocoa depends upon two things;—first the nature of the soil, and secondly, the preparation of the nib after it is taken out of the fruit.

The finest cocoa in the world is grown on one farm in Guatemala, but the natives pay such a high price for it, that there is only a small quantity exported for experiment or, occasionally, as a curiosity. I am informed by a gentleman holding land within a mile of this farm, that they cannot grow such a fine quality or anything approaching it. Seed obtained from this farm has been grown in other localities without any better result than from ordinary seed.

The Trinidad cocoa commands a high price in the market, and an account of the mode of preparation of the nib will, therefore, be of interest to all growers.

The best cocoa is picked from the pod, and the nibs or nuts are then placed in a pile and fermented with plantain or other green leaves for 5 to 7 days, according to the market for which it is intended. The heap will get so hot that the hand cannot be kept in it an instant. The nibs are then taken out of the pile and dried in the sun, and afterwards retain a rounded surface. This treatment makes the difference in the price of cocoa, between 50*s*. and 108*s*. per cwt. Ordinary cocoa is only fermented for three days. The fermentation takes out the better flavor. The Spaniards will pay a very high price for specially cured cocoa. Poor and small seeds cannot support the same amount of fermentation that large, fat, round nibs will. The fermentation destroys the germ of vegetation, and prevents the nib from growing musty.

I have had great success with the live seed collected in Trinidad and on West Coast of Africa, repacked in my own warehouse in London, and re-shipped to Ceylon and Batavia, where it has arrived in good order, packed in earth and moss in Wardian cases.

It will be seen that the quality of cocoa, equally with tea, depends on careful fermentation. It remains to be seen whether the kind of bean or properties of soil have greater influence as to goodness of results.

CONDITION OF THE MADRAS PRESIDENCY.

We append an extract from the Foreign correspondent at Madras of the *Agricultural Gazette*, of December 23rd, 1878, which may be found interesting :—

That the agricultural condition of this Presidency is in a deplorable state, no one who has studied the returns of cropping and stock which are available can doubt. From the former it may astound you to hear that of the area of crops raised.

76·2 per cent,	are	cereals.
9·2	"	pulses.
12·8	"	industrial crops.
2·0	"	garden crops.
100 0		

The garden crops are the only ones which are regularly and systematically manured; a small portion of the cereal crops also occasionally receive a small quota of fertilizing substance, besides what paddy crops get in the shape of the silt, &c., brought to them in the water used for irrigating them. The industrial crops may be classified as follows :—

Cotton	45·5	per cent. of the area occupying them.
Oilseeds	43·5	" " "
Indigo	8·6	" " "
Other crops	2·4	" " "
	100·0	

If we classify all the crops as exhaustive and restorative, supposing that they are properly used, the results will be something as follows :—

Exhaustive crops occupy 93·4 per cent. of the cultivated area.

Restorative crops occupy 6·6 do. do.

There are, however, about 5,000,000 acres of land left idle, "waste," annually ; the total area under crop being about 23 5 million acres ; this land is not fallow, but simply left uncropped for a time. There is, besides the land left "waste," about 1,000,000 acres of land relinquished by the tenants annually, which will no longer produce remunerative crops ; the area annually relinquished has been rapidly increasing of late years, and in this is to be seen confirmatory evidence of the belief in the exhausted condition of our Indian soils, which has, of late years, been gradually growing so universal.

Regarding the live-stock of the country, it may not be uninteresting to note the following figures for live-stock per square mile of territory :—

	Cattle.	Sheep and goats.
Great Britain	... 66·6	325·0
Belgium	... 109·4	68·9
France	... 57·2	131·3
Madras Presidency	... 93·1	76·9

If we also take into consideration the diminutive size of Indian stock, the small number maintained is very striking. If the total number of live stock in this Presidency, according to the latest returns—those for 1872—be reduced to cattle, by calculating five sheep as equal to one bullock, it will be found that for every 100 acres of arable land, there are only 44 head of cattle to provide ploughing power, breeding stock, and manure. The stock per acre decreased in the 15 years before 1872 by over 10 per cent. During the same time the average area tilled by the plough decreased by nearly 16 per cent,—very probably owing to the deterioration of the ploughing cattle. The area of the cultivated land, on the other hand, during the same period, increased by over 17 per cent., showing that the natural grazing or fuel-producing grounds of the country were reduced by nearly 8,000,000 acres. The number of ploughing cattle increased during the 15 years, but that of cows decreased by nearly 14 per cent. Whether the decrease in the five following years has been commensurate I do not know, for, though due in July 1877, the quinquennial returns, from which I take the above figures for previous years, have not yet seen the light of day.

These facts may enable people interested in Indian agriculture to form some idea of what conditions exist—at least in the Southern portion of the peninsula.

GARDEN.

"*Apropos* of trees," writes a correspondent in the Southern presidency, "there is one which I think ought to be planted in every garden in Madras. It is the *Cerbera Odallum*, a native of salt swamps on the coast of Malabar and common in the Maldive and Laccadive Isles. It flourishes exceedingly well in Madras, and I think, nothing can be more refreshing than the white, fragrant flowers with their deep, shining green leaves. Shrubs of the wax-flower plant also grow easily and well here ; its flowers are of a wonderfully pure, soft white, are generally double and fragrant during the night. The large flowered Cryptostegia, a fine twining shrub is doubly useful ; it makes very thick high hedges and yields a fine, strong fibre, resembling wax. It is ornamental too ; I know nothing prettier than its large, soft, rose-coloured, bell-shaped flowers which look exceedingly well with a back ground of deep-green near the snowy wax plant, and the cool white sprays of the *Cerbera Odallum*. All these three species I have mentioned require little coaxing, and flourish with comparatively little care, which is a great consideration. They can stand rain, dry heat and hot winds wonderfully, and the stormy, changeable weather we have had lately has little effect, as far as I can see, on these sturdy growths."

Strawberry plants.—A supply of strawberry plants, of a new species, was lately received by the Government from New South Wales, and ordered to be sent to the Superintendent of the Botanical Gardens, Ooty.

AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

The usual Monthly General Meeting was held on Thursday, the 19th December 1878.

The Hon'ble L. S. Jackson, C.I.E., President, in the Chair.

The proceedings of the last Meeting were read and confirmed.

The following gentlemen were elected Members :—

Messrs. Walter Knaggs, Edward Scarth, Baboo Grija Prosunno Mookerjee, and the Hon'ble Mr. Justice Wilson.

The names of the following gentlemen were submitted as desirous of joining the Society :—

T. T. Leonard, Esq., Bangalore,—proposed by the Secretary, seconded by Mr. W. H. Cogswell.

The Manager, Lallacherra Garden, Cachar,—proposed by the Secretary, seconded by Mr. J. E. Machlachlan.

W. St. Clair Grant, Esq., Latipore Concern, Bhaugulpore,—proposed by Mr. G. H. Grant, seconded by the Secretary.

Manager, Paikpara Estates,—proposed by the Secretary, seconded by Mr. Cogswell.

Rejoined—Major W. Franklin, 2-14th Regiment, Lucknow.

Contributions.

1. The *Indian Forester*, No. 2, of Vol. 4. From the Editor.
2. Proceedings of the Agricultural and Horticultural Society of Madras for past three years. From the Society.
3. Report on the Internal Trade of Bengal for 1877-78. From Government of Bengal.
4. A Wardian case of plants. From the Acclimatisation Society of Queensland.

Garden.

The Gardener's monthly report was read, of which the following are extracts :—

"The work done has been somewhat similar to last month. Road-making, and repairing, tidying up flower garden, &c. The only two remaining *malees* we have, have been engaged amongst the roses, propagating house, and potting."

Resolved, that renewed efforts be made to secure the services of at least six good *malees*, though it may be difficult to do so as the demand for this class appears to exceed the supply.

Mr. Gleeson submits reports on the condition of two Wardian cases of plants received from the Botanic Garden, Singapore, and from the Queensland Acclimatisation Society. Of the former (46) nine have died : of the latter (59) seventeen have died.

It was resolved that the Annual Exhibition of flowers and vegetables be held on Tuesday, the 28th January, and the details submitted by the Council were agreed to. Due notice to be given by advertisement early next month.

In respect to the provision of vegetable and flower seeds for next year, it was resolved that the orders be confined to England and America, as those imported this year from France and Germany, have not been generally well reported on.

It was further agreed that a collection of bulbs and tubers be imported in due season from England, to be disposed of to Members at cost price ; also ornamental plants and fruit grafts on due security being given by applicants as to the amount of cost of the same.

The Council submitted the result of their endeavours in the past two years towards the engagement of a practical entomologist in connection with blight of various kinds affecting tea plants. Several references both by circular and personal application had been made to various agents connected with the tea industry. Some had readily promised to support the scheme, provided others would agree to do so. As however, many, though apparently well inclined, would not come to any definite understanding, the Council now suggested with regret, that the project be abandoned. *Resolved*, that the recommendation of the Council be adopted.

NOTICE OF A PECULIAR PINE-APPLE FROM MYMENSINGH.

The Secretary read the following extract of a letter from a lady correspondent on the above subject :—

"I enclose you a very hasty sketch of a most peculiar pine-apple. It was grown somewhere in these parts and brought in a *dalee* to our Collector who gave it to me. I was inclined to think it was a *Lusus naturæ*, in vegetable life, but he said he thought *not*, and subsequent enquiry seems to confirm this. We hear that one year seventeen were brought from the same place, and another year twelve, and I have been promised a plant of this peculiar pine-bearing species I have not exaggerated one whit, the centre pine was much over a foot long, tapering downwards and terminating in what looked like three fingers. These were nothing but the pine itself extending a little way, (the upper and thicker part of the fingers so to speak) the thinner part being embryo leaves terminating in a little tuft. From the top *seven* smaller pines projected, each terminated by a tuft of leaves. I would have sent you this had it been possible ; but as I feel sure you would be glad to hear of it, I have described it as well as I could. I must tell you that it possessed the full scent of the pine, and when one of the smaller ones broke the juice literally ran from it. Have you ever heard of such a species? Pines are so common in the surrounding districts that they are used for making hedges. We are going to plant all the tufts from off the little pines, or shall I call them pinelets? We hang it up by the stalk, hence my describing the stalk end as the top."

The Secretary added that he had communicated with Mr. John Scott, in reference to the above letter, and he had obligingly recorded the following remarks :—

"I have occasionally seen fruits of the pine-apple very similiar to that of which you send me the sketch and description from your correspondent. The *sorosis* form of fruit (as represented by the pine-apple, the bread-fruit, and mulberry) consists as you know of a shortened spike or raceme in which the tracts and floral envelopes are more or less succulent, united, and converted into a fleshy fruit. Now, as in the case above referred to, some varieties have a tendency to become proliferous, and the individual flowers form separate and independent fruits. I may remind you of the Chinese variety, known as the many-headed pine, in which the individual flowers are all converted into miniature, but perfect fruits, each, as well as the central axis, bearing a terminal leaf shoot.

"Your correspondent's variety differs considerably from this, as would appear from the sketch and description. It would be well worth adding to your collection."

CURIOUS HORTICULTURAL CIRCUMSTANCE.

Read the following note from Colonel W. H. Lowther :—

"For some years past I have been endeavouring to hybridize that beautiful *Convovulus*, *Ipomœa rubro cœrulea*, (the *true blue*) with its white variety. I obtained the seeds of the latter while I was at Jubbulpore, and have for several seasons sown the two mixed together, without any results in variegation, or the originazation of any variation : this cold season to my astonishment, the produce of these repeatedly associated colours, has ended in the whole of my stock being *pure white!* The plants are very vigorous, and are growing in all aspects, sunny, and shady, and in the same rich quality of soil. The flowers are full sized, and are frequently mistaken by strangers for the "Moonflower" (*Ipomœa grandiflora*).

"Is there any recognized law of 'Vegetable Physiology' which can shew a tendency to the 'Albino Type ?' "

Note by Mr. John Scott.—"With reference to the results of Colonel Lowther's experiments in the annual mongrelizing of the white and blue flowered varieties of *Ipomœa rubro cœrulea*. I am not at all surprised. Both in the animal and vegetable kingdom it is well known ; that albinism is strongly inherited. In treating of inheritance in plants Mr. Darwin observes, "that it is a singular circumstance that white varieties generally transmit their colour much more truly than other varieties. This fact probably stands in close relation with one observed by Verlot, namely, that flowers which are normally white rarely vary into any other colour.' 'I have found,' continues Mr. Darwin, 'that the white varieties of the *Larkspur* and the *Stock* are the truest. It is, indeed, sufficient to look through a nurseryman's seed-list, to see the large number of white varieties that can be propagated by seed."

"These remarks of Mr. Darwin's have, however, mainly relation to natural variations, while Colonel Lowther's case is a result of mongrelism. Now, in this as in hybridism, there is nearly in every instance *Ipomœa rubro* a strong tendency evinced in the successive progeny of such unions to revert to one or other parent, so the *cœrulea* case goes to show that as in the inheritance of natural albinism, so in that of mongrelism the albino form is the more strongly inheritable. As an analogous case, I may observe that *Ipomœa purpurea*, which has given rise to varieties varying from blue to dark purple, crimson and white, there is a great tendency, when grown together for successive seasons, in the white variety to predominate, and indeed alternately displace all the others. On the other hand there is no difficulty in keeping up the several varieties when grown separately, so that the former result is no doubt largely attributable to intercrossing by insects."

FIBRE OF MALACHRA CAPITATA.

Read a letter from J. E. O'Conor, of the Department of Revenue, Agriculture and Commerce, forwarding a sample of fibre of the *Malachra capitata* prepared at Bombay and sent to him by Dr. Gray, (Mr. O'Conor's notes on this fibre are inserted in the last published number of the Journal, Vol V., Part 4.)

The Secretary intimated that the Members of the Fibre Committee had examined the above sample and submitted the following remarks thereon :—

Minute by Mr. S. H Robinson.—"I have no doubt this fibre would prove a good substitute for jute for most purposes to which jute is applied : but it seems rather more harsh and its spinning qualities should be tested in one or two Jute Mills before giving a very decisive opinion. To ascertain whether it would prove economically a substitute for jute, we should require to know the yield of fibre per beegah or acre and the cost of cultivation and manufacture."

Minute by Mr. W. H. Ogilvie.—"This sample is beautifully bright and clean, fair length and good strength of staple, but somewhat harsh. I doubt if it would make a good warp yarn in itself, but mixed with good jute it would do so. The fibre for spinning is not so valuable as jute, it lacks the forked ends, when broken, such as the latter possesses, and partakes of the character of the fibre known as 'Meshta,' which, when broken, looks as though it had been cut and left with square ends."

"Before its value as a spinning fibre could be fairly assessed in competition with jute, it would be needful to show cost of production, outturn per beegah, &c." Letters were read—

From Director, Department of Agriculture and Commerce, N.-W. P., submitting for an opinion a small specimen of colored seeded cotton raised in the Etawah district from seed brought from Mecca. This specimen being too small for satisfactory examination, a further and larger quantity has been applied for. The seed has been sown in the Society's Garden.

From J. F. Duthie, Esq., Superintendent of Botanic Garden Saharunpore, forwarding seven different specimens of cotton raised in the garden. Referred to Cotton Committee.

From H. L. LeMesurier, Esq., Minister of Public Works in Egypt, applying for seeds of jute and notes on cultivation thereof. Complied with.

Mr. LeMesûrier applies for seeds of various other useful plants which he wishes to introduce into Cairo. This request is receiving attention.

From the Assistant Director, Royal Gardens, Kew, returning thank, for back numbers of the Society's proceedings.

From the Secretary, Agricultural and Horticultural Society, Madras. Returning their thanks for Journal, Vol. V., Part 4.

For the above communications and presentations the best thanks of the Society were accorded.

BOTANICAL GARDENS AND PARKS IN THE NEILGHERRIES.

WE make the following extract from Mr. A. Jamieson's interesting Report on the Progress and Condition of the Government Botanical Gardens and Parks on the Neilgherries for the year 1877-78 :—

During the past year 746 fruit trees, 2,154 timber trees, 10,084 ornamental trees, shrubs and budding out plants, 3,063 packets of vegetable and flower-seeds, 60 bouquets and 414 baskets of cut-flowers were sold from the gardens.

Potatoes.—Attention still continues to be directed to the cultivation and improvement of potatoes on the Hills. The notes compiled and published by me in August last have been widely circulated among cultivators, and it is hoped that by adhering to the simple rules therein laid down, some good may result. Upwards of 50 maunds of healthy seed potatoes were distributed from the gardens gratis among European and Native cultivators in quantities varying from one to four maunds. The Ootacamund Monigar reported that those supplied to him were a total failure. A report to the same effect was received from a planter at Kulhutti who was supplied with a similar quantity, but there can be no doubt that the non-success in the first instance was entirely due to their having been planted on unsuitable land. The unusually wet autumn of last year was also much against the production of potatoes of good quality. The entire crop on the Hills having been more or less affected by disease, especially where planted on heavy low-lying lands, sixteen maunds of the most improved kinds were imported from Australia this spring. These are now in the ground and look exceedingly promising not having shown the slightest sign of being affected by disease. Their produce will be planted again in October, so we should have at least 100 maunds of sound seed available for distribution in the spring of next year.

Fodder Plants.—In November last 30 lbs. of seed of *Sorghum Saccharatum* and 20 lbs. of Planter's friend (*Sorghum Kaffrarium*) were received through the Commissioner of the Neilgherries from the Superintendent, Government Farms, Madras. This seed was distributed in quantities of 1 and 2 lbs. to planters and others on the Hills and in Wynaad interested in the cultivation of fodder-yielding plants, some of whom have reported favorably on it as will be seen from the annexed extract from letters received from them. A small quantity of each was sown in the Ootacamund and Kulhutti Gardens and in Sim's Park, Coonoor. That sown in the Ootacamund Garden did not thrive, the climate being evidently much too cold for it ; that which was sown at Kulhutti and in Sim's Park has thriven admirably, and is now bearing a heavy crop of grain. This acclimatized seed will be distributed or further experiment this autumn.

Cuzco Maize.—About 12 lbs. of seed (raised in Sim's Park, Coonoor) of this valuable maize was distributed last year. It has proved a great success on the Neilgherries when grown at elevations varying from 4,500 to 6,000 feet, but when grown at lower elevations, it fails to produce grain, and is valuable in Wynaad as a green fodder plant only. Being rich in saccharine matter, it is eaten greedily by all kinds of cattle.

Santung Cabbage.—Last year a quarter of an acre of the garden nurseries was devoted to the production of seed of this valuable plant. This seed has been extensively distributed, and all who have received it (with but one exception) speak of it in the highest terms both as a table vegetable and as green cattle-fodder. The native gardeners around Ootacamund are now growing it largely and seem to find a ready sale for it in the local market. There is not the slighest doubt, but it is the heaviest cropping and most valuable cattle-fodder yet introduced to the Neilgherries.

Prickly Comfrey.—A piece of well-manured ground, 80 yards broad and 40 yards in length, was planted with Prickly Comfrey in June, 1877, but I regret to say, that the foregoing remarks on Suntung cabbage cannot be equally applied to this plant. During the rains and on highly-manured land it yields a fair quantity of fodder, but during the dry weather (or when fodder is most valuable) it ceases to produce leaves. It seems to me to require a long season of rest and even irrigation, and any amount of good treatment will not induce it to grow during the dry season. Many planters in Wynaad and on the Neilgherries, who at considerable expense imported and planted it largely, have now abandoned its cultivation as a total failure. The following few extracts from letters received from planters on the above subjects may be interesting.

From J. Ryan, Esq., Planter, Cherambady:

"The cuzco maize seed you kindly gave me was sown on the 28th December and germinated in five days. It grows luxuriantly, but bears very sparingly; the ears seemed full, but consisted chiefly of fibrous covering. I have preserved the seed to sow again. The sorghum was a great success and bore a rich fold. I hope to plant a small field of it this season. The Santung cabbage grew freely, but with all my care I could not succeed in keeping the ants and insects from it. I shall be thankful for any hints regarding its cultivation you can kindly give me"

From Mr. E. J. DeMeder, coffee planter, Kartary:

"The Cuzco maize seed you supplied me with last year was all put down in my estate at Kartary; every seed germinated to perfection, and the plants grew to about 6 feet high and the cobs were about a foot long and quite full. I had every hope of seeing a fine specimen of maize, and it was my intention to have sent you a few of the cobs when they were ripe, but unfortunately they were all stolen by some of the coolies and I could not get a single cob."

From E. C. G. Brace, Esq., Planter, Kotagiri:

"(a.) *Cuzco Maize.*—I sowed the first lot you gave me about the middle of last year. It grew remarkably well, and I have an average of two good cobs of seed to each plant; unfortunately they ripened their grain in the midst of the north-east monsoon. There is no doubt but it requires a well-worked and heavily-manured soil, if it is to be grown to advantage, and I think if sown so as to come into tassel at the commencement of the dry weather, then cut, dried and stacked as cholum stalks are in the low country, it would cut with an ordinary chaff-cutting machine and afford a large quantity of most nutritious food for cattle during the dry months of the year. I tried a small sowing with the two sorghums this spring, but Badaga cattle got in at it and never gave it a chance while there was a blade left; they *would not touch the sorghum* growing alongside. It struck me as resisting the drought better than common maize. I tried a sowing of *Sorghum saccharatum* and *Sorghum kaffrarium* in early spring; though constantly watered they did not make any satisfactory growth until the fall of the spring showers, and of course having been stunted at the outset, never came to much; at favorable seasons, say from April to November, and with deep cultivation and plenty of manure these fodder plants will grow well, but Guinea and Mauritius grass, ordinary Lucerne, or the new American variety will do much better at a far less cost.

"(b.) *New American Lucerne* (*Alfalfa*).—I put down a small patch of this with the very first showers in rows 9 inches apart and 6 inches in the rows. In spite of being constantly fed down by stray cattle it is doing well; when I grow it again it will be in row 18 inches at least apart and 1 foot in the row. It appears to me to bush out far more than the ordinary variety.

"(c.) *Santung Cabbage.*—With Cuzco maize grown, as I have above suggested, the *most useful* and the heaviest yielding plant yet introduced. Eaten greedily by horses, cattle, pigs, sheep, goats and poultry. I told you last year that I had grown them 4½ to 5 lbs., at 2' X 2'. This spring I grew two rows grown 18 inches apart and 1 foot between the plants. I pulled two average plants growing side by side and they weighed 8¼ to 8½ lbs. respectively; not the slightest doubt but that it stands dry weather better than any of the maizes or sorghums, and will give a remunerative yield even on *unmanured soil.* I am quite certain that in a *single* year heavy crops in succession of Buckwheat, Santung cabbage and Cuzco maizes could be taken off a plot of fairly well-cultivated land with ease. Buckwheat grows remarkably well with me here. I hope this season to commence the cultivation of 5 at any rate, but I hope nearly 20 acres of nearly flat land with fodder plants of all kinds, and in this case I shall be glad to have a little of your wheat-seed for trial. I should be very much obliged if you would get me a few sets of *Reana luxurians* for trial."

From J. Cameron, Esq., Superintendent, Government Botanical Gardens, Bangalore:

"I have the honor to submit brief report on the results obtained at Bangalore from the cultivation of the "Santung cabbage" of which you were good enough to present me with a packet of seed on the 22nd August, 1877. Small packets of the seed supplied were again distributed by me to Messrs. Nagapah and Moonesawmy, Florists at Bangalore, for trial in their gardens. My seeds were sown broadcast shortly after the date of their receipt, and they germinated in about eight days very profusely. The subsequent growth of the seedlings was rapid and vigorous, exceeding that of either lettuce or cabbage at the same stage. The young plants were transplanted into drills 2 feet apart to be finally tested as a culinary vegetable when full grown, but it occurred to me while this was in progress, that if the young tender plants were blanched in the same manner as Endive or sea-kale, an excellent salad would be produced. I regret, however, that more urgent work prevented me from carrying this experiment into effect. When the Santung cabbage were full grown (and they were very large resembling a gigantic Cos lettuce) we had them cooked in the same way as spinach, *i.e.*, minced up and boiled for a much longer period than cabbages generally are. I presented specimens to a few of the leading residents in Bangalore with directions to cook them like spinach, and they without exception pronounced the vegetable a success."

New Plants.—A considerable number of new and valuable plants have been added through exchange and purchase to the garden collection during the past year; the most important being a collection of upwards of sixty species and varieties of New Zealand ferns. These were purchased through Captain Campbell Walker from a nursery man in New Zealand, and with the exception of some tree ferns arrived here in excellent order, and are now established and growing well in the gardens.

A small packet of seed of the true *Cinchona Calisaya var: Ledgeriana* was received from Major Berkeley; from this seed 12 plants were raised. These have been increased by cuttings to 57; a portion of these have been promised to Major Berkeley, but I hope to increase the stock largely by cuttings, so that a good number of plants of this valuable cinchona may be available for distribution next planting season.

In the spring of last year a gentleman resident in Wynaad sent me a small case of Liberian coffee. As he had no experience in the raising of this coffee from seed, he asked me to germinate them for him in the garden propagating houses. This I agreed to do, and succeeded in raising 410 plants, 350 of which were sent to the owner. Of the remaining 60, 30 were planted in the Burliar Garden, 17 distributed to planters in different parts of the Presidency, and the remainder are now in the propagating-house in the gardens.

As directed by G. O., No. 3,060, dated 2nd October 1877, four Wardian cases containing economic plants, and one case of seeds were forwarded in March last to Messrs Nicol and Co., Bombay, for transmission to the Livingstonia Mission in Central Africa. The cases contained—

	Plants.
Cinchona Succirubra and C. Condominea	228
Tea Assam Hybrid	138
Coffee Arabica	100
Orange	6
Leechee	7
Nutmeg	2
Cinnamon	2
Jalap tubers	6
Ipecacuanha	12

in addition to a large parcel of cinchona and low-country seeds sent by Dr. Bidie. The gardens supplied seeds of twelve varieties of Australian Eucalypti and Acacia Jalap Taraxicum, Digitalis, Cuzco Maize, Santung Cabbage, Brazil Cherry and the Hill Guava or Goosberry. The plants and seeds were securely packed, and it may be hoped that the greater portion of them will reach Africa in good order.

A case of Neilgherri orchids, indigenous tree, and shrub-seeds, was sent to A. Lascelles, Esq., Wellington, New Zealand, in exchange for Araucarias and New Zealand plants and seeds.

A parcel of cuttings of Rheea (*Bohemeia nivea*) was supplied to the Madras Municipality for trial on their Sewage Farm.

Monsieur Pierre, Director of the Botanic Gardens, Saigon, visited the Ootacamund Gardens in December last, and was supplied with a complete collection of specimens of the different species and varieties of cinchona cultivated on the Neilgherries, also with a number of specimens of the indigenous shola trees.

A case of scions of the finest kinds of apples, pears and plums, cultivated in Australia was imported this season for the purpose of grafting stocks in the gardens, but unfortunately they were all dead when they arrived here, having been packed in too green a state. Another attempt will be made to introduce them this season.

The catalogue of timber trees, shrubs, and flowering plants, &c., for sale at the gardens has been carefully revised and 200 copies printed. They can be had gratis on application at the garden office.

Medicinal Gardens.—Early in 1877 proposals were made to Government by the Surgeon-General, Indian Medical Department, pointing out the desirability of establishing a garden for the cultivation of such medicinal plants as were likely to thrive on the Neilgherries, with a view to reducing the Home charges for drugs. Under G.O., No. 432, dated 3rd April 1877, funds were allotted and measures taken to start an experimental garden. For this purpose a piece of land adjoining the cinchona plantation at Dodabetta was taken up, fenced and drained, and is being planted up as fast as plants are available.

Operations were commenced by propagating the hardier kinds, *viz.*, Jalap, Peppermint, Digitalis, Rhubarb, Taraxicum, Lavender, Rosemary, and Ipecacuanha, the latter being propagated in the hot-house in the Ootacamund Gardens and planted out at Burliar.

(*a.*) *Jalap.*—The propagation of the Jalap plant has been carried on rapidly. At the outset the stock was comparatively small, consisting of a hundred large plants that were grown in the gardens for their flowers only. These plants were lifted, cut over, and the cuttings put in pots under glass, where they rooted rapidly. The number of young plants now planted out in the garden exceed 5,000, and I hope to have at least double that number planted out by the end of this year; 800 of the plants put out in June last have tubers averaging 1 lb. each in weight The original tubers, one of which weighed 15½ lbs., were sliced and dried. A sample of this dried root was sent to the Surgeon-General, Indian Medical Department, for trial in the Madras Hospitals. That gentlemen reported that the root was administered in the form of a compound powder, and in the dose prescribed in the Pharmacopœa for the Mexican Jalap root, and in twelve cases in which it was tried produced precisely similar effects. A 4 lb. sample of the same root was forwarded to London in January last, and has been most favorably reported on. There can be no question that the climate and soil of the Neilgherries is most favorable for the production of this medicine, and if a sufficient acreage is brought under cultivation we will be able to supply the whole of India with this drug at a much cheaper rate than what it can be purchased at in the English market.

(*b.*) *Ipecacuanha.*—The propagation of the ipecacuanha is being successfully continued as will be seen from the following figures. At the commencement of the year under report the entire stock of plants and cuttings in the propagating-house in Ootacamund was 2,698; these have been now increased to 6,956, *viz.*:—

Planted out in the Burliar Garden	2,900
Plants in pots at Ootacamund	3,000
Root, stem, and leaf-cuttings in do.	1,056
Total ...	6,956

which shows an increase in stock during the twelve months of 4,258 plants. The plants at Burliar continue to make a satisfactory growth, notwithstanding their having suffered from the extremes of drought and excessive moisture experienced during the spring and autumn of last year. The plants put out this season are being planted in the warmest and most sheltered parts of the garden.

(*c.*) *Peppermint.*—The area at present under peppermint is not so large as I expected, in consequence of an error having been made at the outset in the propagation and planting of what was believed to be the true peppermint, but which turned out to be another variety of mint. Plants of the true *Mentha piperita* having been secured, upwards of 2 acres have already been planted with it, and as it can be rapidly increased by division of the roots, the acreage under it will be largely extended during the year.

(*d.*) *Rhubarb.*—Our stock of this plant is still very limited. The older plants not having yet produced seed, the propagation has been confined entirely to of-sets from the parent roots.

(*e.*) *Digitalis and Taraxicum.*—Two plots of ground have been planted with Digitalis and Taraxicum sufficient to supply the annual demands of the Medical Department. These plants grow very freely in Ootacamund, and require but little care or cultivation.

(*f.*) *Rosemary and Lavender.*—Several thousand young plants of each have been propagated in the garden nurseries and will be put out in the medicinal garden in October next.

Drugs supplied.—Sixty-five lbs. of Berberis cortex and 62 lbs. of Digitalis folio were supplied to the store-keeper, Indian Medical Department, during the year. Of these drugs we have now in store 15 lbs. dry Jalap root, 50 lbs. Digitalis folio, and 5 lbs. Taraxicum root. Surgeon-Major Bidie, M.B., was supplied with small samples of the following drugs grown in the Ootacamund Garden for transmission to the Paris Exhibition:—Digitalis Taraxicum, Peppermint oil, Rhubarb, Jalap, and Berberis cortex.

A large number of recently imported Australian and New Zealand trees and shrubs have been put out in the Park Many of these thrive much better in Coonoor than in the Ootacamund Gardens. Fifty plants of the valuable cinchona calisaya received from the Assistant Superintendent, Neddivuttum Plantations, will be planted in a sheltered corner of the Park in October next. As cuzco maize thrives splendidly in Coonoor, a small quantity is grown annually to raise seed for distribution.

Burliar Garden.—The nurseries in this garden have received special attention, and are now large enough to admit of a constant supply of young spice and tropical fruit-trees being raised to meet the increasing demand from planters and others for such plants. 289 plants of various kinds were sent out, and the nurseries contained 1,213 seedlings on the 31st March last. This number will be largely augmented during the current year.

To prevent over-crowding, several large Jack trees were cut down and replaced by cocoa, mangosteen, and other more valuable plants.

The West African coffee plants continue to grow luxuriantly, and are evidently quite at home in the climate of Burliar. The largest plant is now upwards of 8 feet high, and is bearing a good crop of plump, healthy berries. Thirteen plants were raised from some seed yielded by this plant last year From information I have received I believe Liberian coffee has not been a success in Wynaad, except where it has been planted in warm, sheltered localities. That it will not grow, much less thrive, in the elevated districts in which the coffee Arabica flourishes, is a point now fully settled. It requires a very much warmer climate than that variety, and in my opinion cannot be grown successfully in Southern India at an elevation over 2,500 feet Our plants were badly attacked by leaf rust in the autumn of last year, but this disease does not seem to affect the health of this plant to the same extent as it does the common variety.

Some hundreds of young plants of *Pithecolobium samon* or rain tree has been raised from a packet of seed received from the Conservator of Forests.

The Mahogany plants put out last year are making a healthy growth, the largest plants now being over 5 feet high.

Cocoa (*Theobroma Cocoa*). In consequence of light crops and a succession of bad seasons in the coffee districts of Southern India, it is not surprising that planters and others are now turning their attention to the cultivation of cinchona, cocoa, and other plants that many prove an equally remunerative and less precarious investment. That cocoa will flourish in many of the coffee estates at elevations from 1,000 to 3,000 feet in Wynaad and Coorg, I have not the least doubt. It might be planted with advantage between the rows of coffee bushes and in avenues along estate roads. In the spring of last year, I distributed gratuitously a number of plants and seeds to planters, who find it thrive and are now anxious to obtain large supplies of plants. Already several thousand seed have been sent to estate proprietors in Mysore, and I have registered orders for the whole crop of seed that the trees at Burliar will yield this season.

The mangosteen trees blossomed very profusely last year, and are now bearing a heavy crop of fine fruit, a small proportion of which will be reserved for seed.

Kulhutty Garden.—The garden at Kulhutty was visited by the Superintendent four times during the year. His Assistant (T. Burrows) was also sent out several times to inspect work, sow seed, and graft fruit-trees. The privilege of collecting and selling the fruit in this garden from August 1877, to 31st March 1878 was put up to auction at the Commissioner's Office and realised Rs. 601.

A good stock of young fruit-trees has been maintained in the nurseries throughout the year. A few pounds each of Sorghum, Planters' Friend, English wheat, and barley have been sown in this garden, simply to keep up a supply of these grains for distribution.

The jalap tubers, rhubarb, and other medicinal plants planted last year at Kulhutty have not thriven so well as at Ootacamund; their cultivation will, therefore, not be continued.

The apple, pear, orange, and other fruit-trees have become so badly affected by parasites that they will soon cease to yield fruit. If it is considered desirable to maintain a fruit garden at Kulhutty, the whole of the old trees should be up-rooted and healthy young trees planted in their places. But as all the fruit-trees and plants cultivated at Kulhutty can be grown equally well at Coonoor, would respectfully beg leave to recommend that the former garden be abandoned and sold. I have no doubt but it could be readily disposed of to one or other of the planters whose coffee estates adjoin the garden. The amount realised by the sale might with advantage be expended on the erection of a permanent fence and the formation of nurseries in Sim's Park at Coonoor.

FORESTRY.

SOME months back the Inspector-General of Forests under the Government of India, forwarded to England through one of the Calcutta agency firms a supply of woods, the residue of the collections prepared for exhibition and other purposes to test practically the value of these woods for carriage building, furniture, turning and other work. Messrs. Mackenzie Lyall & Co. undertook to send the supply and signified their willingness to send further shipments either from Rangoon, Moulmein, or Kurrachee. The woods were offered for sale by Messrs. Churchill, of London and some of the lots realised good prices; specimens of boxwood realised as high as £7 per ton, and if there had been competition, higher prices would probably have been obtained. The Inspector-General of Forests is of opinion that the Conservators of Forests in the presidency towns may, with advantage make selections of woods for transmission to England.

WE learn from Rangoon that the Forest Department contemplate establishing an office and an experimental garden to be conducted on the same principle as the Magagyee plantation at the new head-quarters of the Tharrawaddy district. An Assistant Conservator will be placed in charge as soon as the services of one are available.

THE report for the Tenasserim circle of the British Burmah forests contains an interesting account of the Akyaw or eagle-wood which grows on the islands of south Tenasserim, the produce of *Aquilaria agallocha*, a large tree with a white soft wood. The eagle-wood is found in old trunks, in the midst of decayed wood, forming irregularly-shaped lumps of hard and scented wood. It is collected by the Selungs, chiefly between April and July, and is sold to Chinese traders. The quantity collected annually is

estimated at 1,000 *viss*, valued at Rs. 10,000. The destruction of these trees is considerable, and it has not yet been possible to take steps to protect them.

DESTRUCTION OF TREES BY FUNGI.—The following suggestive paragraph occurs in a letter on Continental Science in the *Madras Mail* :—

In the Cevennes, Upper Italy, Bayonne, and even the Azores, the chestnut trees, which are veritable "bread-fruits" for the population, are dying off; the most vigorous in the course of two or three years. The branches wither from the tips, and a dry-rot eats inwards towards the trunk. Around the roots is a kind of humid gangrene, giving off a liquid which blackens the soil; this inky color, however, may be produced by the tannin, which the tree contains, coming in contact with salts in the soil. On close examination, a fungus, or mushroom, will be found to have entwined itself round the roots, stretched its filaments in the new wood of the trunk and branches. The malady is contagious and re-calls the mulberry disease of 50 years ago. Now all these symptoms coincide with the premature death of the trees on the Boulevards of this city; and beneath the grating, which runs around the trunks, quite a "bed" of venomous mushrooms are even to be found. The usual explanation given for the perishing of the trees in Paris is, the gas pipes and the shaking of the ground by the passing vehicles.

IT is stated that the newest financial project of Russia is in the form of a concession for a term of years of all the State forests to a joint stock company, who will have the exclusive right of cutting and selling timber from those sources in return for a stipulated royalty, to be paid annually to the Government. Among other conditions of the concession, the Company is held bound to re-plant woodlands that have been already denuded by injudicious forestry or by theft, and to conduct their own felling operations with due regard to the interests of the future.

MAHOGANY SEED.

THE following letter was addressed by the Conservator of Forests to the Madras Government on the 16th November last :—I have the honor to inform you that I am of opinion that the Mahogany seed should be forwarded direct from Jamaica or the Bahamas; it should be removed from its capsules and packed in perfectly dry silver sand, or in perfectly dry saw-dust and charcoal-dust mixed; there should be no unavoidable delay in its transport. The box should be addressed to the Conservator of Forests, Madras, and be labelled *Mahogany Seed*, and there would be a better chance for a greater retention of vitality if the box came *viâ* Bombay instead of Madras. On a former occasion a large box was sent, I think, from Jamaica; the large round fruits or capsules had been packed whole with the seed in them, and when opened were found to have quite rotted away, and I afterwards heard that the box had been detained many months in England. It would be too expensive to think of getting live plants down from Calcutta, and far preferable to procure the seed direct than to indent on supplies that had gone first to Calcutta. His Excellency the Governor of Jamaica will be addressed in view to a supply of Mahogany seed preserved and packed in the manner indicated being sent direct to this Government by Mail Steamer *viâ* England and Bombay to Madras.

MINERALOGY.

A CORRESPONDENT of a Madras newspaper has been making a tour of inspection through the gold fields of Wynaad, and in the course of his travels was introduced to Mr. Brough Smythe, and his practical miner, Mr. Laing, who he says came to India to determine whether payable gold is or is not to be found in this country; and they have settled that question beyond dispute. "There is gold and rich gold, but India will never be a mining country like Australia, and for this reason, it can never be properly prospected. It may be asked why it can never be prospected; the answer is very simple, it is broken up into too many proprietorships. What with rajahs, zemindars, and planters, men whose profession and livelihood is gold-digging will never come out here to prospect, *because there are no mining regulations*. One of the first things Mr. Laing said to me was "India can never be like Australia because there are no miners' rights." That has been my impression all along and I told him so. If the gold industry in India is intended to be developed for the benefit of the many instead of the few, then mining rules should be drawn up and copies forwarded to the "Mining Departments" in the various colonies for publication. Of course landholders will do all in their power to oppose this, as they will say the mining rights are already theirs. But they will find it far more difficult to raise capital to work mines in India than it would be in any other part of the world. Both Mr. Brough Smythe and Mr. Laing agree that some of the gold that they have found is far richer than anything of the kind they ever saw in Australia and they showed me some enormous quantities of very rich specimens. They neither of them believe much in Wynaad as an alluvial digging except on Vellera Mullah, which I mentioned in my last as giving good indications of alluvial gold."

PROFESSOR Mendleeff disputes the accuracy of the view generally held, that mineral oils result from the decomposition of organic substances, on the ground that no Devonian or Silurian deposits are met with in Pennsylvania, and that consequently such oils must have been formed in still older strata, which contain little or no organic remains. He believes that in the centre of the earth there is an enormous mass of metal, and especially of iron, more or less carbonated, and that these metallic carburets are decomposed under the influence of water, heat, and pressure, giving rise to the formation of metallic oxides and hydrocarbons.

A MANILA newspaper announces the discovery of a mine of *Amianthus*, or earth flax, in the island of Luzon. Several specimens of that mineral have been sent to Manila and shown to different qualified persons who have pronounced it to be of excellent quality.

THE IRON WORKS AT WARORA.

AN article that appeared in the *Pioneer* some weeks ago contrasted the success attained by the Bengal Iron Works Company, in the manufacture of iron on a commercial scale, with the complete failure of the Government Works in Kumaon, and with the not very successful results of Government enterprise in the same line at Warora in the Central Provinces. We were then inclined to attribute the partial failure of Mr. Ness's experiments to the fact that he was a Government servant, and therefore probably to some extent hampered by official rules and red tape; whereas, the manager of the Bengal Works had only to do what he considered best, and render an account of his stewardship to the company that employed him. This theory, however, appears to have done injustice to the Government of the Central Provinces; for, on searching through the notices of the Warora Iron Works, that are published in the official reports of the Public Works Department, we find that every facility has been given to Mr. Ness to pursue his experiments in his own way, and that his failure to produce pig iron by the usual process must be attributed to the imperfect nature of the materials he had to work with, the want of experienced assistants, and the circumstance that his whole time and attention could not be given to the iron-smelting experiments alone, the management of the Warora Colliery being also in his hands.

Of the three raw materials required for the production of cast-iron—ore, limestone and coal or coke—only the last is of a poor quality in the Central Provinces, the limestone of Bailgaon and Kundalla being very good, and the ore by all accounts only too rich. The following tables give a comparative view of the compositions of the iron-ore and coal employed in two places where cast-iron has been successfully manufactured, and at Warora, where the manufacture of this form of iron has been a failure. No. I represents Derbyshire clay ironstone (calcined) and Derbyshire coal as employed before the introduction of high furnaces and coke fuel; No. 2, the raw materials employed in the Raneegunge coal field; and No. 3, the materials employed at Warora. The limestone used may be considered nearly equal in quality, that employed in Bengal being the worst :—

Ore	No. 1	No. 2	No. 3
Oxide of iron	60	66	95
Silica	26	10	5
Alumina	7	7	traces.
Lime, potash, Phosphoric acid, carbonic acid, &c, ...	7	17	—
	100	100	100

Coal	No. 1	No. 2	No. 3
Fixed Carbon	67	56	56
Volatile combustible matter	23	23	20
Water	8	4	10
Ash	2	17	14
	100	100	100

It is evident from these figures that the iron-ore of Lohara and Pipalgaon, used at Warora, is immensely superior to either of the other two, being, in fact, nearly pure magnetic oxide, whilst the coal is superior to that of Raneegunge, in-as-much as it contains less ash. The worst quality about the Warora coal is the large proportion of water it contains; but in Mr. Ness's opinion the greater part of this is only held mechanically, as in a sponge, and will disappear when the mine is better drained.

Considering the excellence of all the materials employed in the Warora experiments, so far as can be judged from their chemical composition, it is natural to inquire why iron has not been successfully obtained from them on the large scale. The answer would appear to be that the Warora coal has one great defect that does not appear in an analysis table—when heated it decrepitates and crumbles to powder—and that possibly the assistance of an experienced furnace-man in constant attendance would have rendered the experiments successful. Another point to be borne in mind is that the blast furnace in its present form has been evolved from the experience of generations of iron smelters, who worked with the poor clay ironstones of the English coal measures, and that, therefore, in principle it is presumably better adapted to the reduction of poor ores like those of Raneegunge, than of the rich oxides found in the Central Provinces. Mr. Ness's furnace was a little one, twenty-five feet high, with three twyers or blowers. The blast was heated and driven in under a pressure of about three pounds to the square foot. The coal with which the furnace was charged was found to burn away rapidly, and the ore was reduced to metallic iron at a comparatively low temperature. The mass of metallic iron, instead of combining with carbon from the heated coal or the furnace gases, to form the fusible mixture called cast-iron, settled down on the hearth of the furnace in the solid state, and though the temperature in front of the twyers was raised to the point at which the firebricks began to soften, the mass of iron refused to melt. Now in a discussion of these experiments, it appears to have been the opinion of a distinguished English ironmaster that success would probably have been attained if a somewhat larger furnace had been used, with a blast pressure of twelve pounds or so to the square foot, sufficient to force the air up through the mass of materials filling the furnace instead of allowing it to be wasted about the twyer holes, *and if the furnace had been charged at first with a poor material* (a mixture of clay and limestone with very little ore) so as to form a large quantity of fusible slag, through which the spongy iron might descend slowly, absorbing carbon on its way.

It would, however, be almost an insult to the pure ores of Lohara to treat them in this way, and we therefore think that Mr. Ness was quite right to abandon the attempt to make cast-iron and go in for the production of malleable iron and steel by a direct process. That he has been perfectly successful in this, so far as metallurgical processes are concerned, our readers are already aware. It remains to be seen whether the manufacture will pay commercially.—*Pioneer.*

THE WYNAAD GOLD FIELDS.

MR. BROUGH SMYTHE has submitted to Government a further report on his explorations at Devalah and other parts of the Wynaad. He writes :—"As early as possible after the date of my last report I caused mining operations to be carried on in an adit near Wright's level, north of and, about 30 feet below the point where the rich auriferous quartz occurs, and in a sinking about 3 feet, stone has been obtained in which much gold is visible. Quartz from this adit, in which no gold was to be seen, has yielded at the rate of 2 oz. 11dwt. 18 5 grs. per ton. The old adits made by the natives in one portion of the cavern reef have been cleared, and gold is to be seen in the 'casing' of the reef ('hanging wall') The yields lately obtained from this reef have been as follows :—

	OZ.	DWT.	GRS.	
Quartz, no gold visible ...	0	11	15·5	per ton.
'Casing,' small particles of of gold to be seen	0	11	16	„

The native miners appear to have taken stone principally from the 'foot wall.' This reef will be further tested in sections. A vein of quartz near the Prince of Wales' reef has been opened, and the only parcel of quartz yet treated has yielded at the rate of 17 dwt. 11·77 grs. per ton. Further trials of the stone from this locality will be made shortly. Quartz broken out of the Korumbar reef, the outcrop of which is about twenty-two chains north-easterly from the cavern reef, has yielded at the rate of 1 oz. 0 dwt. 1·15 grs. per ton. A reef south of the road from Nelakotta to Sultan's Battery has been partially explored, and some of the stone has been tested, but only a minute quantity of gold was found—not a weighable button. All the soils in the vicinity of the reef yield gold by washing, and it is certain that if mining operations be pursued, the 'run' of gold will be found in the reef. Other reefs in the neighbourhood of Devalah and north and east of Devalah are being opened. On the 9th November I went down the Carcoor Ghat. At a point about 1,900 feet below Devalah, I found a thick reef in the jungle; and at Karambaut, in the Kaleikapoya, about 2,600 feet below Devalah, there is a large area which has been worked by the natives; and on the hills, for a distance of a mile or more, there are blocks of quartz indicating the occurrence of a reef of enormous thickness. Soil taken from the bank of the stream was washed and gold was found, and the Korumbars made a sluice (not down to the bed-rock), and they also got gold. Subsequently I had stone broken out of the reef at various points; and on returning to the camp Mr. Thomas Laing washed some of the broken quartz and found gold. The yields have varied from a mere speck of gold to 9 dwts. 11·13 grs; 17 dwt. 23·38 grs.; and 1 oz. 4 dwt. 14 grs. per ton. Near Murada, about 2,750 feet below Devalah, there is a large vein of quartz outcropping in the stream, and there are two reefs parallel to the main reef-the one about five chains and the other about seven chains north-easterly from the stream. The main reef is traceable for more than a mile-and-a-half. The Korumbars inform me that these reefs have never been worked by the natives, nor have they washed the soils for gold. I took samples of stone from each of the reefs, and, I found a few minute specks of gold in each. A little less than one mile south-west of Eddacurra, more than 2,800 feet below Devalah, there is a strong outcrop of quartz. The stone has yielded a little gold. On the road from Eddacurra to Nadukani three large reefs and numerous small 'leaders' were seen. Not much progress has been made with the survey of this district during the past month; my visit to Eddacurra, the testing of quartz, and other urgent work having occupied a great deal of my time. With the permission of his Grace the Governor, I propose to visit Charambadi and Vellirymalla next week, in order that I may gain some knowledge of the rocks and veins in the western part of the district; and on my return I shall devote myself wholly to the completion of the map and the examination of the reefs in this area."

IRON IN THE SIMLA HILL STATES.

IRON is found chiefly in the British tahsil of Kotekhaie, and the native States of Bissahir and Jubal.

In Kotekhaie the mines are situated on two different mountain spurs close to each other.

The first—known as MOLTANN is near the village of Trola, about 6 miles N. E. of the dâk bungalow at Kotekhaie.

The second-called TUMBARAN is at the foot of the village of Degwari Jubal.

At the former there are three extensive subterranean galleries from one of which the natives draw their mineral, whenever they can procure charcoal for its manufacture. The iron is procured in grains, (like sand) from a micareous schistose matrix thickly encrusted with small (imperfect) garnets. Though the surface schists are ferruginous, they are less so than those extracted from the interior of the hill, which are much softer in composition and are more easily reduced to powder, due to their being permanently exposed to damp which greatly assists in their disintegration.

The ores yield magnetic oxide of iron as follows :—

Moltann	19·33 per cent.
Tumbaran	28·47 „ „

This difference, though, does not prove that the latter is richer than the former, but more than likely is owing to the variableness of the specimens.

The iron is smelted in April-May, after the snow is melted, and again from September-November. During the rainy season the manufacture is stopped.

The mines are worked by running a horizontal shaft, only 3½ feet in diameter, into the side of the mountain: the schistose matrix, containing the iron grains, is brought out in skins, reduced to a fine powder, washed in the stream, and the grains of iron smelted. When reduced into small pigs, it is again put into the fire, and hammered until it becomes malleable. All these processes are performed on the spot. The furnaces are nothing more than large clay crucibles, about three feet high, not unlike two inverted cones the diameter in the centre being about eighteen inches. There are two holes at the bottom, for the insertion of the nozzles of two bellows The crucible, being placed over an ash-hole, is filled with grains of iron (ore), fire applied, and the bellows worked. When sufficiently fused, an iron rod is struck though the bottom of the crucible, upon the withdrawal of which, the impurities run into the ash pit, leaving the iron in the crucible.

The tools employed resemble somewhat those sketched in Colonel Yule's *Note on the Iron of the Kasia Hills*, in vol IX, page 857, of the Journal of the Asiatic Society Bengal.

About three hours walk from the foregoing mine, are those of SHEEL in the native territory of Bissahir, Here the ore occurs in talcy schists, it is the same as the Kotekhaie description in all other respects: as also the manufacture.

There are about a dozen small smelting furnaces, worked to suit the convenience of the work people (who are also small farmers), though for the Rajah's profit.

Here, most of the tools used in constructing the Hindostan and Thibet road, were manufactured under the superintendence of Captain D. Briggs.

About two thousand maunds (80lbs, to md.) of iron are exported annually from the mines of Kotekhaie and Sheel to Simla and the plains; some to Thibet *viâ* Rampore.

Another three hours walk from Sheel brings the traveller to the small rest house in Deora, in the native territory of the Rana of Jubal.

In this territory the iron occurs in three hills named Jachali, Panati, and Praonti. Proceeding from Deora in the direction of Kotekhaie, and about six miles off is JACHOLI on the right of the road, on the left is PRAONTI, while PANATI is on the slope facing Jacholi.

There are about a couple of dozens of smelting furnaces, but owing to a scarcity of fuel they are worked at irregular intervals.

The ores yield magnetic oxide of iron as follows:

Jacholi	19 to 33 per cent.
Praonti	20 „ 25 „
Papati	17 „ 22 „

Reckoning two maunds of charcoal as being necessary to the production of one maund of pig iron, it gives an annual consumption of 4,000 mds. of charcoal for the production of the 2,000 mds. of iron before alluded to: 4,000 mds. of charcoal represent 20,000 mds. of wood, equal to 2,000 trees—at which rate per annum the districts are being denuded of their arborescent covering without any means being adopted to reboise them. The forest revenue is almost *nil*, and the supervision (in Kotekhaie) corresponds. With a good system of forest conservancy, notably a proper course of felling by rotation and rest, and a resident European Forest official, these ferruginous districts would yield a large quantity of iron, and could then be profitably worked under skilled European superintendence.

The Rajah of Sirmoor established, sometime ago, a large iron foundry at his capital of Nahun, but owing to a want of judicious management it has come to nothing. It seems to have been treated as a fog with the ordinary result of such treatment. Under proper supervision the foundry and workshops could have become of great benefit to the neighbourhood for many miles round.

The pig iron costs from six pice to two annas a seer (2 lbs. av.) at the works. About one-third loss occurs on working the pig into tools or in refining. The hire of a mule carrying 2½ mds. (200lbs) costs 12 annas a stage. Tools for digging cost from 5 to 6 annas a seer.

The mines are situated 35-43 miles E. of Simla; the marches being SIMLA to FAGU, 11 miles, dâk bungalow establishment and provisions; Sainj, 7 miles, no accommodation; KOTEKHAIE, 14 miles., dâk bungalow, but without any establishment; DEORA, 11 miles, rest-house, but no establishment: provisions and luggage coolies procurable at all the stages.

G. P. P.

The Planters' Gazette.

TEA.

THE imports, stocks, and deliveries of Indian tea from 1st January to 30th November, stands as follows for the years respectively mentioned:—

	1875. lbs.	1876. lbs.	1877. lbs.	1878. lbs.
Import	22,306,000	25,844,000	28,458,000	30,239,420
Delivery	21,262,000	21,782,000	25,533,000	34,180,950
Stock	8,190,000	10,280,000	14,496,000	11,142,280

Thus the increased import in London since 1875 is 7,933,420. It will be seen that while the deliveries showed an increase in 1878 over the previous year of 33 per cent., the imports give only an increase of 6 per cent., and it is hardly likely that the subsequent shipments will bring stocks in hand up to as high a figure as the previous season's returns showed.

NATIVE TEA GARDENS.

WE are extremely glad to see native enterprise spring up in the cultivation of tea. We have heard of several new gardens being opened in Assam and Cachar by natives, and we personally observe that a good number has been started and managed by natives in the Darjeeling district. Amongst them we feel great pleasure in noticing to-day the plantation of the "Hindoo Tea Co., Ld.," which has been opened in the Terai by a number of young and energetic Hindoo gentlemen. In the last season an area of 60 acres was planted, and the Company has arranged to extend 40 acres more in the coming season. A plantation of 100 acres is of course of some worth, and it will be a credit to the Company if they can manage it with the present number of paid-up shares.

For some time past we heard a complaint against the management, but we are now glad to see that the past management has been done away with, and the business of the Company is now in the hands of a Secretary who is an intelligent practical man and has taken up the work in right earnest. The present Manager is said to have vast practical experience in tea. The budget of expenditure for the coming year framed by the new Secretary and Manager which is now in our Press, reflects much credit, and shews how economically the natives can manage such affairs.—*Darjeeling News.*

TEA STATISTICS, 1876-77.

(RESOLUTION BY THE GOVERNMENT OF INDIA.)

IN 1872, the Local Government and Administrations were asked to prepare statements illustrative of the position of tea cultivation in India. The statistics which were furnished in reply to the request then made were so much delayed that, having regard to the rapid development of the industry, they were of but little value by the time the whole of the replies had come in. The Governor-General in Council considered last year that it was desirable, in view of the great extension of this industry, that the Government and the public should be possessed of statistics showing its actual condition in each province of the empire from year to year; and, accordingly, a circular was issued in May 1877, requesting that the tables circulated in 1872 (the forms being, however, materially simplified) might be filled up for the last two official years. A similar return for coffee cultivation was also asked for.

2. The replies to this circular have been greatly delayed, but are at last complete. The returns from Assam for tea, and from Madras for coffee, were particularly late; and as the production of tea in Assam, and of coffee in Madras, is larger than in any other province, the delay in both these cases is much to be regretted. It is hoped that, in future, earnest efforts may be made to transmit these returns within the time prescribed, *viz.*, in three months after the expiry of the year to which they relate.

3. The figures furnished by Local Governments have been thrown into two general comparative returns for 1875-76 and 1876-77: one relating to tea, and the other to coffee cultivation. Copies of these returns will be forwarded to her Majesty's Secretary of State for India, in compliance with his Lordship's request, and the returns will be published in the volume of miscellaneous statistics relating to British India, which is about to be issued by this department.

Copies of the returns will also be forwarded to the Local Governments and Administrations, through whom the figures from which they have been compiled were furnished.

4. The returns are defective in several points, as shown in the foot-notes appended to them, and in the returns themselves. The Governor-General in Council invites the attention of the Local Governments and Administrations to these defects, and will be glad if they will correct and complete the returns, so far as may be possible, excepting in regard to columns 13 and 14 of the tea statement, the information given in which is not now required.

5. It has been represented that considerable difficulty has been experienced in obtaining from planters the information required for the preparation of the tea return. This difficulty is possible caused by planters not knowing why the information is wanted, and not being assured that the figures they may furnish regarding their own estates will be kept private. The Governor-General in Council desires that the Local Governments and Administrations will be good enough to cause it to be explained, in future, to all planters from whom information may be sought, that the statistics are required for the preparation of returns for the whole of India, similar to those which have now been prepared; while all information given as regards particular plantations will be regarded as strictly confidential, no use being made of it except as material for the compilation of the general returns. Copies of the returns which accompany this Resolution should be sent with a copy of the Resolution to each planter from whom information has been received, in compliance with the requests made by Local Governments, and copies should be sent regularly to all those from whom information may be obtained in future. With this explanation of the objects sought by Government, and with the omission of the columns above specified, it is hoped that any objections to the communication of information which may have hitherto been entertained by planters will no longer be felt, and that they will cordially assist in rendering the returns accurate and complete, and in enabling the Government of India to issue them promptly and punctually.

6. In letter No. 1,183, dated the 28th March 1878, the Government of Bengal ask for further instructions in regard to the preparation of future returns of tea cultivation. The points on which instructions are desired relate to the figures to be entered in columns 5, 6, 13, and 14 of the return. As regards columns 13 and 14, it has already been said that they may be omitted from future returns. In regard to columns 5 and 6, the way in which these should be filled up has been defined in letter No. 448, dated the 25th October 1877, *viz.*, that tea plants should be considered "mature" when three years old, and "immature" before they reach that age. This definition should be adhered to.

7. The Government of Bengal also state that it is inconvenient to prepare the returns for the official year, and suggest that they should in future be made out for the calender year. The Government of India have no objection to this being done; and future returns, for both tea and coffee cultivation, may be made out for the calendar year.

8. Returns of tea cultivation in the North-Western Provinces and British Burma, and of coffee cultivation in Coorg, for the official year, 1877-78, have been received. Returns of tea cultivation in Assam, Bengal, the Punjab and Madras, and of coffee cultivation in Madras and Mysore, are still due; and the Governor-General in Council requests that they may be furnished at the earliest possible date. Where information has already been collected for the official year, the returns may on this occasion be made out for that period.

* No information available.

† For 165 plantations in 1875-76 and 146 in 1876-77 the figures are merely estimates, no returns having been received from the managers. The figures in column 12 are not trustworthy owing to want of complete figures for the area of land under mature plants.

‡ The figures from this district are for the calendar years 1875 and 1876.

‖ Not including some plantations existing in 1876-77 for which no returns have been received.

§ The figures for 1876-77 are exclusive of 6 plantations in the Kumaon District and three in the Garhwal District.

Note.—The figures in column 12 do not in all cases correspond with those obtained by dividing column 5 into column 11, owing to errors in the local returns from which this table has been compiled.

* No information available.

† For 165 plantations in 1875-76 and 146 in 1876-77 the figures are merely estimates, no returns having been received from the managers. The figures in column 12 are not trustworthy owing to want of complete figures for the area of land under mature plants.

‡ The figures for this district are for the calendar years 1875 and 1876.

§ Not including some plantations existing in 1876-77 for which no returns have been received.

‖ The figures for 1876-77 are exclusive of 6 plantations in the Kumaon District and three in the Garhwal District.

NOTE.—The figures in column 12 do not in all cases correspond with those obtained by dividing column 5 into column 11, owing to errors in the local returns from which this table has been compiled.

LEAF-DESTROYING CATERPILLERS.

WITH reference to the remarks in our January issue, on the tea-leaf destroying caterpillars, the following will be of interest :—

To

The Secretary Board of Revenue.

SIR,—With reference to the Board's Proceedings No. 2956 of 4th November 1878, I have the honor to report that the caterpillars from Coonoor sent to me are the larva of some moth belonging to the Tortricida or leaf-rollers.

2. Some of the species are very destructive to the vine, oak, roses, and other plants, and the one now existing near Coonoor might become a very serious pest on tea estates, were it to increase to any considerable extent.

3. I regret to be unable to offer any suggestion with a view to the destruction of the caterpillars. Their natural enemies, the birds, will no doubt destroy many of them, and climatic influences may also help to reduce their numbers.

I have, &c.

(Signed) G. BIDIE, *M. B., Surgeon Major,*

Madras, 12th November 1878.

LAHARDUGGA.

(FROM OUR CORRESPONDENT.)

Palamow, New-year's Day.

THE whole of the jungle and young sâl trees have been frost-nipped and are shedding their leaves, as also plantains and ornamental shrubs around the bungalow. Fortunately, tea bushes are not so delicate and have stood out the frost fresh and green, save a few of the delicate pure Assam *jât.* Of these the oldest leaves suffer from the frost, but, strange to say, the tender shoots, left from the last plucking, remain intact. To guard against sudden changes of weather—for heavy hail falls here—tea seedlings should all be covered with a cone of thatch. This is not expensive, and makes certain of the plant being protected from accidents of any kind till spring arrives, when of course it must be removed. It seems strange that those persons who have ventured into tea operations, should confine themselves chiefly to the vicinity of Ranchi. The lease-holds about there are not pucka, and present land-holders may probably find to their cost that when the gardens become valuable, and yield a large outturn, the rightful owners will turnup to claim the whole. In this sub-division there are thousands of acres of Government waste lands which can be leased from the Crown, and Chota Nagpore is the fountain-head from which pours the stream of the best tea garden coolies.

The whole country is covered with sâl forests. Why Government should reserve extensive tracts of them, decimate whole villages and turn the "reserve" into a wilderness, is puzzling indeed to the uninitiated, sâl logs cannot be floated down the mountain streams, owing to boulders and cascades and to carry them out of the "reserves" by cooly labor would not pay. The villagers, being ousted out of their old homes, emigrate to the tea districts; and from these they seldom return, owing to the high rate of wages. Should they return, it is merely a run "home" to spend their surplus cash, to astonish their relatives, and induce them also to emigrate to the Eldorado. There are, however, thousands left who benefit by farming the absentees' land, and tea planters need never trouble their minds up here on the score of labor. The pay is from two to eight pice according to age, and to the work done per diem. No risks are run by large advances or epidemics. Once the confidence of these semi-wild people is secured, you can do anything with them as regards factory work; they are as impulsive and confiding as children, and become attached to the employer and garden.

MOSQUITO BLIGHT.

THESE insect pests, it is known, are increasing in their destructive efforts on the tea plants of Assam and Cachar. It has been argued that their presence is the result of exhausted soil; and where young estates, opened out on rich virgin soil, have suffered, a cause has been sought for in the seed from which the plant was raised: impoverishment of the soil is the argument, and doubtless the conscientious belief of many able men, whilst others seek immunity by a more careful selection of seed. A remedy is also sought in extra cultivation and in using manure; still the pest is present, and we know many promising estates where, though soil, seed, and position have been all that could be desired, and labour superabundant, yet nevertheless the Garden has been almost black, and the crop of the season ruined by this dreaded mosquito,—devouring wood as well as leaves, and sucking out the very core of the young stem.

We were much interested some time ago to learn that the "Asiatic Society" had this matter under consideration, and that a practical entomologist would probably be brought out from home to make a lengthened tour throughout the tea districts with a view to study the subject of these insect-blights, so as to better understand them and admit of a remedy being adopted. We know this measure has the approval, and would receive the support, of several proprietors, but we apprehend it is not acceptable to all. We presume it would be difficult even for the "Asiatic Society" to trace and find a remedy for this growing serious evil, in a way that would be approved of by every planter; and hence the evil is perpetuated. It were better perhaps, then, for a few earnest men to carry out such an undertaking, even though many hold back, than to left it fall through. A very few maunds of tea would represent Rs. 1,000, and Rs. 15,000 is we believe all that will be required to support such an enquiry, and carry it through for two succeeding years,—time sufficient to exhaust the subject thoroughly, and probably lead to a comprehensive system which would return, even to a dozen contributors, if they each had 500 acres of good Garden, the cost of such an enquiry by the gain of the first season.

The planters as a class hold varied views regarding these pests. Some hold that the mosquito cannot be destroyed until the surrounding country is thoroughly drained; and consequently they see no remedy; others dread the proximity to forest lands; whilst others argue that mosquitos migrate, and are capable of flying in a brief period a distance in search of food. But those all, earnest men, appear to lose sight of the fact that the mosquito is a pest that was unknown until within the past few years, and that it is now becoming more destructive every season.

We believe, however, that the evil may be remedied, and we trust, for the sake of this large industry, that the few who can influence the many will unite in organising and carrying out this scientific and practical enquiry; and, if possible, endeavour to stamp out this growing serious evil.

A correspondent sends us the following memo, on the subject of Blight, the result, he says, of considerable experience by a practical man, on a badly blighted garden:—

Split dry bamboos, make into convenient size bundles, set fire to same and apply in the following manner:—One coolie at either side of the bush to hold the lighted bamboos or torch underneath, and shake about so as to disturb the insect, but at the same time not to injure the leaves or bushes; another coolie to hold a torch over the bush, which will be found to singe the insect in its endeavour to escape; every blighted leaf to be carefully plucked immediately after, and what is not fit for manufacture, to be burned or otherwise destroyed; and should this course not prove quite effective the first time, the blighted bushes might be gone over again in a similar manner.

Having requested one of our managers on a blight-affected garden in Cachar to carry out this plan to the letter, we have the following from him, dated Cachar, 5th November 1878:—

"I had the piece of tea affected carefully gone over with blazing bamboos, and the following day I had every leaf that was in the least marked by blight carefully plucked as directed. I found that for nearly six weeks there was little or no appearance of blight, but after that it made its appearance again and is now nearly as bad as ever. I feel certain that if the plan were carefully carried out, and commenced when blight makes its appearance on small patches of tea, that a great deal could be done in the way of checking blight."

What we understand by this is, that the experiment was so far successful but that the re-appearance of the blight was due to its presence on patches not operated on in the manner described; and that, to render the cure in every way effectual, it must be begun before any advanced stage of disease is reached. This is true, no doubt, and it is far better to essay a remedy in time than to wait till the blight has got too firm hold of a garden, when it is difficult if not impossible to eradicate it. It would be far better to sacrifice a patch of cultivation at an early stage of the appearance of blight than to permit it to spread, as, for want of precautions taken in time, is too often the case.

Blight seldom attacks at one and the same time, or at all equally, the whole of a garden, and there is good reason to believe that, were vigilant care used in discovering the earliest indication of blight, and prompt and decisive measures adopted for stamping it out when it first appeared, the extension of the evil might be considerably diminished."

COFFEE.

WE hear that the Chief Commissioner of Mysore has granted the petition of the Munzerabad Planters' Association to permit Mr. Harman, the Superintendent of the Bangalore Experimental Farm, to visit their estates to investigate leaf-disease.

A CORRESPONDENT writing from Peermed, Travancore, in December says:—

"Crops of coffee up here are turning out as much and more than estimates; very little light floating coffee, in comparison with the last two years. New clearings for coffee are being felled in spite of the leaf-disease appearing year after year. Some tea has been planted in forest soil and promises better than on grass lands, although the value originally of the forest was Rs. 1 per acre against Rs. 2 now for grass land. The land, 30,000 to 60,000 acres that has been taken up by Messrs. Munro & Co. in north Travancore on the Cardamon Hills is being opened in coffee, tea, and cinchona; it belonged to a petty Rajah who paid a subsidy to the Maharaja of Travancore."

The manufacture of chicory and fig coffee in Austria has made great progress, and now reaches about 250,000 metrical quintals annually. Bohemia stands at the head, where large establishments carry on the manufacture; Styria, Meravia, Vienna and its environs Carniola and the Tyrol may also be mentioned.

We believe that a planter in Ceylon has offered to settle down in Burmah with the object of cultivating coffee and cinchona, if the Government will offer liberal inducements.

The coffee leaf disease has broken out badly on the plantations in five districts on the west coast of Sumatra, and in four other districts a different disease said to be caused by insects, and which attacks the roots of the plants, is doing much damage. In parts of Java the sugarcane has been attacked by swarms of rats, in such numbers that parties of natives offered rewards for killing them, bringing in from 600 to 1,000 tails daily.

AGRICULTURE FOR COFFEE PLANTERS.

By A. C. Dixon, F.C.S., M. R. A.S.E., B. Sc. & Sci. M.B., (London.)

All matter is organized or unorganized. The latter constitutes the mineral kindom ; the former is subdivided into the vegetable and animal kingdoms. The vegetable is formed of the elements of the mineral re-arranged into forms of greater complexity. The animal organ re-arranges the vegetable into still more complex forms ; but both at death resolve back into the simpler compounds from which they were derived.

Now man is altogether dependent on the vegetable, either directly or indirectly, hence it is of vast importance to him, so to work the soil to produce vegetable matter, suited either for his own sustenance or for that of animals with which he works, or upon which he may feed. Nature has clothed the earth with vegetation which may yield sufficient food for a time without trouble to a small population, but with increase of population we must have increase of food material, and so it has become necessary to cultivate systematically the most suitable forms of vegetation. This constitutes agriculture—it may be for the production of plants chiefly for seed, or for roots, tubers, bark, fibre, leaves, herbage, or forage. In Ceylon we have instances of all these. The seed crops, however, predominate.

It is not sufficient to find that a certain area of the earth's surface yields a certain crop in abundance without much trouble, and removes its produce from year to year, without returning any equivalent to the soil. If such a course be pursued, we may soon expect to exhaust its power. In order to maintain it, we must return certain incombustible elements to the soil, and in order to fully understand the life, history, and the manipulation required in the raising of various crops successfully, we must consider the bearings of several branches of natural science. For example, geology to give us an insight into the characters and capabilities of the soils in different areas; chemistry, to tell us about the compositions of the soil, plants, and manures with which we feed it ; botany and vegetable physiology for understanding the laws of growth and development of plants ; heat, light, and electricity—how they influence plant life ; meteorology, to give us an idea of climate; animal physiology for the proper treatment of animals employed ; and, lastly, mechanics, to guide us in the use of tools, machinery, &c., connected with various crops. From this we see that agriculture, is not, as many suppose, a mere mechanical art, but a comprehensive science, embracing the principles of many departments of knowledge, all of which have rendered important services.

The causes which have operated to retard its progress are numerous. Those referring particularly to this island, we shall not dwell upon at present. The soil with which we work is somewhat complex. Chemistry has resolved all matter, whether solid, liquid, or gaseous, into an alphabet consisting of about sixty-five elements. Now, out of these we have to deal mostly with the following :—Oxygen, hydrogen, nitrogen, carbon, phosphorus sulphur, chlorine, silicon, potassium, sodium, calcium, magnesium, aluminium, and iron. These occur in the soil in various combined forms, of which we shall have to say more hereafter.

Plants are generally regarded as ternary compounds, consisting mainly of carbon, hydrogen, and oxygen. Nitrogen, however, is one of their essential elements and several others occur in small quantities. Animals are mainly quaternary, consisting of carbon, hydrogen, oxygen, and nitrogen. That which remains after burning a plant is the inorganic or incombustible constituent ; the other portion passing off, the combustible or organic.

Seeds which contain the germ of the young plant, when surrounded by suitable conditions, *viz.* moisture, a certain amount of heat, and air, germinate or begin to grow, sending forth tap roots as in coffee, or adventitious roots, as in paddy, into the earth, and a stem into the air. It continues to grow until it reaches maturity, or until its parts are no longer able to perform their functions. Its period of life may be less than a year, as paddy, or it may be long lived, as coffee. The food of the plant must be in a liquid or gaseous form. The liquid is taken up by the root hairs. This is accomplished by the joint action of several forces, such as *capillarity*, where the liquid food ascends tubes constituted of narrow cells, by the same force that ink travels along blotting paper. This is assisted by a pulling force due to the evaporation of the watery part of liquid food from the surface of the plant, so inducing more to ascend ; and this is still further aided by the force of *osmosis* or interchange of liquids of different specific gravities, when separated by any organized membrane. When such is the case, there is always a tendency to establish an equilibrium of density, and to produce this, the external liquid must receive a portion of that within, and so we have a double current, the one inward, called *endosmose*, the outward *exosmose*. The liquid taken up by the root hair is of less specific gravity than that already in the cells, which has been thickened by loss of water due to evaporation. By the combined action of these forces the crude food is carried up to the leaves, there to be elaborated by the action of light and heat, and so made fit for its growth and nourishment. As long as these root hairs find sufficient food, and there is freedom of circulation, the plant will continue to thrive, hence we see the importance of having the soil in such a condition as to allow these root hairs to traverse it easily.

As every cultivator should be able to act the part of doctor to his various crops, he ought to have some general knowledge of the structure and functions of the principal parts or organs. Just as words are composed of syllables, and syllables of letters, so plants of tissues, and tissues of *cells*. A cell, therefore, is regarded as the most elementary part of its structure.

The stem consist of various tissues, each having a certain duty to perform. They are built according to two great plans, the one with its woody tissues in rings, as in the coffee, the other irregular, as in the cocoanut palm. Let us take for illustration the coffee stem. We have a soft tissue at the centre called pith, surrounded by a woody tissue, which increases from year to year in ring-like fashion. This tissue is succeeded by the cambium or formative layer, and that by bast. From the cambium region, wood is added internally, and layers of bast, (a very useful product in many plants, *e. g.*, for making gunny bags) are added externally. This bast is surrounded by the epidermis or outer bark. The duty of some of these tissues is to transmit, that of others to secrete.

Next we come to the leaf. This is a flattened expansion of the stem, having corresponding parts. Its purpose is to expose to the greatest possible extent the amount of crude food taken up by the root, and conveyed by the stem to be exposed to the action of light and heat, there to be assimilated. Leaves are provided with stomata, or little pores, through which they can take in or give out gaseous matters. They take in carbonic acid gas, given off by animals when they live, and they give out oxygen to carry on the life of the animal. We have thus seen that a plant may be said to absorb, breathe, assimilate perspire, and excrete.

Flowers, which appear at some period of life in the higher plants, and when ripe become fruit, are for the purposes of reproduction. In many cases we often reproduce from a cutting placed in the ground, or upon another stock.

A complete flower consists of four series of organs. The outermost is the calyx or cup ; the next the corolla. These organs serve to protect the more delicate organs within as well as to attract insects which aid fertilization. We next come to the stamens, or male element of the plants and then the pistil or female portion. After fertilisation is effected by the pollen from the stamens, that part of the pistil called the ovary, containing the seed or seeds, increases according to the nourishment supplied. It ripens and becomes fruit. These last organs, when the flower is in bloom, are easily injured by wind and rain, and so affect the crop of fruit to a great extent. These injurious influences may be absent, and yet, although flowers were abundant, the fruit may be small, owing to the tendency of a plant to make wood or leaf, from which its attention may be diverted in some cases, by pruning the stems, or in others the root.

Now let us consider more in detail the soil, or decomposed outer portion of crust of the earth, as well as the great mass of liquid water upon its surface, and the air by which enveloped. First as to its origin : this takes us far back into the history of the earth. How formed in the first instance, we will not venture to say at present. The great changes of the three great masses of matter, the storms of

land as earthquakes, the storms of water and those of the atmosphere, have played a very important part in making it what it now is. Just as the animal, vegetable, and mineral are necessary to keep up equilibrium of action, so two great antagonistic forces in the earth,—the levelling and elevating—keep it in equilibrium. As one country subsides, another is up-heaved slowly; as one tract of land sinks down, and may be entirely lost, as islands at the present day in the Pacific ocean, so another is up-heaved, or it may be a new island appears out of the water. Constant change is going on. The aqueous and atmospheric agencies tend to plane all down to a level, the volcanic agency, or that resident within the earth, to produce unevenness. The rocks here have been thrust up by volcanic agency. No doubt, Ceylon was once united to the main land of India, that the land subsided and left this an island, and that we are now slowly rising again. We have plenty of evidence in proof of this. These vast masses have been carried out by the action of water in the form of rivers, carving their way through the softer portions from the higher grounds to the lower.

The hard or soft portions of the earth, whether exposed to the air or deeper seated, are either of volcanic or stratified origin, which last may have been greatly affected by heat, and so become metamorphosed or changed, sometimes so much as to be confused with strictly volcanic. The stratified are so called, because they have been deposited in strata or layers by water, in a somewhat uniform manner, just as strata are now being deposited in lakes and oceans of the present day. In many countries, these different strata, which once formed the beds of ancient seas and oceans, and of which we have but little knowledge, save by fossil forms of plants and animals that found a resting place there, may easily be made out, sometimes occupying a flat area, in others, out-cropping and forming ridges or hills. It is somewhat difficult to make out the stratification here, though it can be seen in a few places.

The hard rocks so abundant in the hill country or underlying the the cabooks in the low districts, are known to geologists by the terms granite and gneiss, with other names denoting rocks near akin to these.

The three elements of granite are quartz, felspar, mica, of gneiss the same, but in the latter case the minerals are more in layers than arranged promiscuously. Passing through the country, we see these vast masses, some standing out more prominent than others, namely, those which have had the greatest power of withstanding disintegration. On looking at many of these, we may notice how the rain is gutting them on a minor scale, just as the whole mass has been gutted by our great rivers. These disintegrated rocks on the slopes of the hills form the soil of the planter, while those of the flatter regions form soil adapted to various other forms of vegetation. All have a use and can be turned to practical account. In some cases, we have the surface soil composed not of the decomposed rock upon which it rests, but of matter transported from other localities, from which it has been washed, such as great alluvial tracts.

As vegetation has flourished upon the surface, so the rocks, whether hard or soft, have become decomposed, in some cases to a considerable depth. This action continued through long ages, and aided by decaying vegetation, has formed what we call a virgin soil,—soil which has had all its own way up to the time the cultivator takes possession, then to be directed anew into a fresh line of action.

The soil therefore in the main depends on the rocks from which it is derived. Yet the soil here must not be pronounced bad or non-fertile: many of the soils are good and capable of very great development: they require proper handling. The English soils were not brought to the state they now are in a brief period. The rivers to which I referred are gradually scarping out the land at a slow rate, and transporting thousands of tons of good soil per year, as well as large quantities of good plant food, more especially from the slopes of the hills, where the water falling acts as a scoop to convey the virgin soil, or the rich carbonates produced after a burn—hence the wisdom of breaking the force of the running waters and their contents by terracing and giving it a good chance to be absorbed by deep cultivation, just as we have a pulling force acting on the leaves inducing the crude food to ascend so we have on the face of these terraces a pulling force, the sun tending to pull the moisture through, and the air after it, thus inducing a free circulation.

According to the steady action of the internal heat of the earth, and pressure to which the strata have been subjected in long periods of time, we get strata of different densities. Here we have a dense one of gneiss or granite and other kindred rocks which by disintegration have yielded a soil having properties dependent on its component minerals, modified by decayed vegetable matter, called *humus*. The color of the soil depends partly on this humus as well as on various oxides of metals, notably iron, which gives reddish hues similar to rust. So we, have black, chocolate, reddish, and yellowish red soils. The color too affects the power of absorption of heat a dark soil possessing that property in a high degree for the same reason the floor of the barbacue is made black in preference to any other, in order to absorb the heat readily.

As to the chemical composition of the soil, *quartz* is a chemical compound not a mere mechanical mixture of the elements, silicon and oxygen. It may be white as found on some estates, or of a yellowish tinge as sea sand, or other colour as jasper, agate. This is a very insoluble substance, and is a great agent in keeping the soil open. *Felspar*, a mineral of various colours, is chiefly of two varieties—potash and soda. The common form here is, potash felspar. It is chiefly composed of silicic acid, potash and alumina. The alumina is the great retentive agent for moisture: mica is a glistening mineral, scaly or in plates composed of silicic acid, alumina, potash and iron, smaller quantities of other minerals such as hornblende, epidote, &c., occur here and there.

Dolomite, a double carbonate, that is, a carbonate of calcium, (the base of lime) and magnesia, is also found in large masses in some parts of the Island in a highly crystalline form.

Cabook met with abundantly in the low country, is of the same composition as gneiss, from which it has been derived by decomposition. A lime formation, a sort of breccia,—occurs in the Northern Province.

Since the crops here are of a permanent character, not so much attention has been given to the preparation of the soil previous to its being expected to do duty for a number of years. In some cases, the idea is to get the portion cleared and plant into the ground at once, forgetting that it cannot be meddled with, to any great extent, in after time. It is necessary that there should be a free internal circulation in the shape of drains, and the soil in a good physical condition, and that to a good depth.

Now with respect to the physical state of a soil. It is composed of particles of various degrees of fineness, some as fine as flour, others pebbles, and in some cases large boulders of undecomposed rock. Now the finer the state of division,—provided it be not too much so as to form a sort of paste when moist—the more work it is capable of doing. The deeper we go from the soil to the subsoil, the more compact we find it. The more open it is, the greater the surface exposed to the action of air and water and the greater the absorbing power for gases brought down by the air. We get a similar idea of this great absorbing power of gases from charcoal, when we use it, say for absorbing the gases resulting from the decay of meat, or for absorbing the coloring matters from sugar.

The soil must be somewhat of the nature of blotting-paper, and the ingredients—potash, phosphoric acid, and others—must occur in the soil in two different forms of combination; the one chemical, the other physical; the former being ready to be acted on, and brought into solution to take up the latter state, and so distributed, physically, through the soil: in this form only can it be made use of by the plant. Hence the difference between cultivated and uncultivated land; and just in proportion as these matters occur in a physical state, so will the soil be able to nourish the plants placed upon it. In order to bring the other portion into use, we must have the presence of moisture, a certain amount of heat, and plenty of air!

Tillage, or breaking up the soil, multiplies the surface exposed to the action of air; and this requires to be done to prevent a maximum of such surface, just as the stem is spread out into leaves, to be exposed to the action of air, light, and heat.

The question as to how much of the nutritive substances a soil must have to yield good crops, is a very important one; but difficult to answer. The nutritive power depends on the quantity of such in physical combination; and if chemical analysis cannot distinguish the chemically combined, we need not expect a satisfactory answer. For a long time, cultivators and chemists thought that by analyzing a soil, all the difficulties would be solved; but experience has shown, and is still shewing, that in may cases it does not assist in improving the soil, nor yet tell why certain crops fail, such for instance, as the recent, analysis of soil on the Kaluphana estate. We have apparently similar soils as Kahagalla, producing good results. This plainly shows that the analysis of soil, as usually performed by chemists, does not always afford a sufficient guide to the capability of the soil; nor yet to tell us the kind of manure particularly well adapted for crops required.

The detailed analysis of a soil, gives only the proportions of its different constituents, and these, without any reference to the state in which they are combined.

Such analyses are often disappointing in their practical bearings; hence the need, not of a chemist, pure and simple, but of an agricultural chemist; and by this I mean not one who can only estimate the elements in a soil, measure, or produce, but at the same time who has studied the effect of different manures on different soils, and their different modes of action, just as a doctor knows that what will do for one person, will not be suitable for all—there are constitutional differences in soils, as well as in human beings.

Yet chemical analysis has done much, and furnished reliable information on several points. It tells us what kinds of artificial manures are best suited for soils differing in composition: whether special manures or lime may be applied with advantage: whether we may burn clay, and use it with profit, whether non-compounds produce humus whether some valuable ingredients are in the soil in excess, which might be beneficial in a more diluted form; and lastly, whether any given element is not in sufficient abundance,—*Ceylon Times.*

ANTIDOTES TO LEAF DISEASE.

Udapusellawa, November 9th, 1878.

SIR,—I noticed, in a late issue of your paper, your allusions to my experiments with sulphur, as a cure or antidote for leaf disease. I should have pre ferred to remain mute on the subject for some time longer, until I could speak with absolute certainty on the subject.

What made me first think of sulphur, was seeing the French peasantry industriously dusting with it every leaf of the vineyards in the neighbourhood of Mentone as a cure for oïdium. That disease is marvellously like that which we are endeavouring successfully to combat: indeed, I fancy that it requires the microscope to detect the difference; to my unaided eyes they seemed identically the same. On my return from wintering in France to England, I sought for information regarding the progress of coffee cultivation in other countries, and asked particularly if leaf disease had been noticed. In Trinidad, Mexico and Guatemala a very superior coffee is grown: indeed the finest sample of coffee, as regards length, compactness, and regularity of size of bean, which I have ever seen, was grown on the sierras of Mexico. I am satisfied from all that I have read,

and from all that I could learn from residents in some of those countries, that Central America is, as yet, *free* from the disease.

Early this year, I met a Dutch gentleman, who is part proprietor of a large coffee estate in Java. He had been on a tour through the coffee districts. His remarks shewed him to be a gentleman of great intelligence and a close observer. He was positive that no leaf disease had been seen in Java, and also mentioned that the finest estates in that island were in the neighbourhood of extinct volcanoes. This helped to confirm the idea that had been for some time in my mind, that volcanic countries are free from leaf disease, because their soil is impregnated with sulphur. If it is a fact that the pest has appeared in Brazil, it would only confirm the likelihood of my theory, for I believe that empire is geologically similar to Ceylon, with a primitive formation of granite and gneiss. In April last we had a slight attack of leaf disease on this estate. I had only a limited supply of sulphur at the time, but applied what I had, liberally and freely dusting the trees and mixing a handful with the soil round the roots. The disease completely disappeared within a month, but unfortunately for my theory, it also, a little later on, left the coffee on which there had been no application. The effect, however, on the disease was very marked. I am now prepared with a good supply of sulphur and am watching for the first incipient signs on the leaf, which presage an attack, to try again. I am satisfied that if the application will not prevent the disease, it is at any rate a palliative that hastens its departure. Lately, one nursery, about five acres, was attacked and in a short time was as yellow as gold, so bad that I thought a portion of it would be snuffed out altogether. I applied the sulphur when my stock arrived, and now it is as green, and healthy a lot of plants as one would wish to see. The difficulty was, in this case, brushing the sulphur in amongst the leaves, the plants being so closely packed together.

I consider it proved, beyond a doubt, that in small areas as a nursery the disease can be banished, with ordinary care in applying sulphur, in time.

Whether it can be driven out of an estate is as yet "*not proven*."

On our nine hundred acres of coffee we have not at present a diseased leaf, but if the enemy appears I am prepared to fight him. Until I have had more experience in this matter, it would be foolish to speak positively, or confidently; but if I gain the victory I will not fail to let my brother planters know.

Another point, which others as well as myself should try to determine, is whether sulphur is an antidote to the disease; whether a timely application, enabling it to permeate the system of the tree, will give immunity from all attack. The field that suffered here last year was bearing 10 cwts per acre, and ripened it, nearly all, although it lost a deal of leaf.

I presume that the germs of the disease are there amongst the fallen leaves. I intend giving this field a dose in February or March just before the time when I expect the disease to appear, if it appears at all.

I am as yet an enquirer and do not arrogate being the discoverer of a positive cure. I am groping in the dark, looking for light, but I think so far, there is no reason to be discouraged.

Since Messrs. Matheson & Co. began to work the Rio Tinto mines in Spain, they have discovered literally a mountain of sulphur. They use it for smelting the copper pyrites, yet have sufficient to supply wants of the world.

Flower of sulphur costs about Rs. 5 a cwt, in London, but in a crude form could be shipped, at the port of Ferrol, for probably less than half that price, should an extensive demand for it spring up in Ceylon.

This Government should follow the example of the French, by passing it free over the Ceylon Railway and declaring it free of all import duty. —*Ceylon Observer*.

G. A. DICK.

THE *Ceylon Observer* has received from the Secretary to the Planters' Association, the letters we reproduce below :—

DEAR SIR,—As I understand that it is not improbable that some attempt may be made to arrest the ravages of *Hemelia vastatrix*, I shall feel obliged if you will lay the following suggestions on the subject before the Committee of the Planters' Association. At the same time as I offer these suggestions, I wish it to be distinctly understood that they are only suggestions, and as such must commend themselves to the common sense of planters generally before they can be adopted. Should any or all of them be adopted, it must be on the responsibility of planters themselves, and no responsibility must attach to me if after considerable outlay the results should, not be what were hoped for. In what follows the *general* habit of the fungus only is treated of.

The disease, it is believed, is conveyed into the leaf during wet weather, when the stomates are more open than usual. After remaining there for some weeks, dry hot weather causes it to produce fruit on the outside. This fruit forms the orange-coloured blotches by which the disease is readily recognized. In districts with well-marked wet and dry seasons generally, the chief outburst of this form of the pest is shortly after the rains have ceased. In the Pussellawa district, where the rains mostly cease about the end of the year, it is generally I believe, about the end of January or early in February. There will also probably be similar but less pronounced outbursts when the dry interval between the S. W. and N. E. monsoons is very decided. This being the case, the best time to attempt to arrest the spread of the disease is, whilst the dry weather fruit is coming to maturity; for it is evidently impossible to save the leaves that have once become infected and the only reasonable plan is to destroy them as soon as possible I have reason to believe that the sporanges (orange dust) require to be sometime exposed in a dry state before they become capable of germination and that they do not germinate readily when quite fresh from the tree and retaining their bright orange tint.

To destroy these sporanges ought to be the chief object, before they become scattered; as they will be, when ripe, under the influence of the wind. I would therefore suggest that:

(1) All diseased leaves that may fall from the trees be at once carefully gathered in bags and burnt—the bags should be made of some close material to prevent the escape of the sporanges, and be disinfected frequently.

(2.) Where proprietors can afford it, the diseased leaves should be carefully picked from the trees and burnt, soon after the attack has fairly manifested itself.

(3) All prunings, whatever the time of year, should be carefully burnt at once.

(4.) The stems and larger branches of the trees, ought to be well washed in the middle of the dry season with a suitable solution for destroying the parts of the fungus that may be clinging to the bark. Kerosine, carbolic acid, Condy's fluid mixed with water or a solution of lime or sulphur, would, I believe, answer the purpose.

(5.) All the ground in the neighbourhood of the trees, roadways as well, should be sprinkled with quicklime, in the middle of the dry season.

(6.) A second sprinkling of lime a week or two before the end of the dry season or between the two monsoons would increase the chance of killing the sporanges.

(7.) All decrepit trees that do not pay for cultivation and only serve as a breeding ground for the pest, should be cut to the ground.

(8.) An isolated valley like Maskeliya or Pundalueya is favorably situated for trying these experiments, which can scarcely be tested fairly in less than two years.

(9.) Keep on manuring as usual.

(10.) Notice carefully the patches on an estate where the disease is worst, and find out the reason for this in regard to situation, &c., so far as possible. Notice if the disease is worse near any particular trees or plants, decaying timber or vegetation of any kind.

(Signed) R. ABBAY,

Little Bromley, Manningtree, Nov. 5th, 1878.

To the Secretary of the Ceylon Planters' Association.

Little Bromley, November 21st, 1878,

DEAR SIR,—In my letter to you of November 5th in reference to the treatment of coffee estates and coffee trees in order to get rid of or mitigate the ravages of *Hemelia vastatrix*, I suggested the use of kerosine as a wash for the trees. It has occurred to me since then that the inflammable nature of this liquid would render it dangerous if used, especially in the dry season. No doubt the same objection has already occurred to practical men. I would therefore substitute for kerosine the words "urine from cattle establishments, especially when fresh." Will you also add to my suggestion about picking diseased leaves from the trees the words "where specially practicable."

I remain, &c.,

(Signed) R. ABBAY.

To the Secretary of the Planters' Association.

Apart from burning with fire and quicklime, it will be seen that Mr. Abbay recommends certain washes. Amongst these was kerosene, but he recollected its inflammability and advised the substitution of a substance which is in reality, apart from its possible effect on fungi, the best possible form of liquid manure. The truth is, however, that kerosene has been already widely used by planters as a wash for the stems of trees, with reference to the attacks on the roots by white grubs, mealy bug, and fungi not allied to leaf disease, which Mr. Abbay has told us is *sui generis*. But, of course, the kerosene was used in a highly diluted form, as we suppose it would be by any person applying it for leaf disease.

NEW METHOD OF HOLING STEEP LAND.

A CORRESPONDENT of a Ceylon contemporay writes concerning an experiment as carried out on about three acres of a steep new clearing on the Uva side of Nuwara Eliya. It was planted up during the last south-west monsoon with coffee and cinchona.

A man and a boy take a line between them. The former with his mamoty knocks the peg well into the earth and then proceeds to cut away the soil all round. When finished the cutting consists of the following dimensions, *viz.*, about 18 inches on the upper and $2\frac{1}{2}$ feet on the lower side and 2 feet in width; the depth will of course depend on the slope of the hill. The steeper it is the deeper the cutting.

The boy with a small alavange or pickaxe (without the handle) now sinks a hole in the centre 15 inches deep and 6 wide ; this is filled up with surface soil and is then ready for the reception of the plant. Between them the two coolies cut a hundred holes. The cost therefore is much the same as ordinary holing. Now for a comparison between the two methods.

At present, holes are cut for the express purpose of forcing on plants, after which to say the least they are useless. Indeed there is reason to believe that in some soils more harm than good is done by holing. For instance in clay lands after the young roots have penetrated the soft soil and come into contact with the outside of the hole, they receive a sudden check which must prove hurtful to a tree just at the time it wants most nourishment, for it would then likely be about 18 months old.

In the new methods we have firstly a deep narrow hole surrounded with a cleared space which hereafter can easily be loosened up as the plant grows "thereby gradually introducing the roots into the soil."

Secondly, the soil is opened up to the beneficial action of the sun.

And, thirdly, the ledges or terraces, while the clearing is new, will be the means of accumulating a part of the surface wash ; and eventually the constantly falling leaves. They will furthermore do duty as manure holes. But enough has been said to show that whilst in one case an expensive work is undertaken for a single and doubtful object, in the other we have for a similar outlay, work which will not only be beneficial at first, but will remain a lasting benefit so long as the estate exists.

So much attention has been directed recently to the future of coffee culture in Coorg, that Mr. Lewis Rice, the Director of Public Instruction, Mysore and Coorg, has devoted several pages in his *Gazetteer* of Coorg, recently published, to the subject. Mr. Rice has had ample opportunity of enquiring into the present state and future prospects of coffee-culture in Coorg and therefore we must give some weight to his opinions. We cannot help thinking, however, that some of Mr. Rice's arguments are inconsistent. In one place he remarks :—" Coffee may yet succeed in Coorg, and the undaunted planter may yet have his reward if the method of cultivation best suited for each locality is carefully adopted, and if, with the increase of jungle vegetation, especially bamboos, better seasons may be expected to return and the white borer to disappear." The impression left on the mind of the reader—and it is the correct one,—is that the white borer still pursues his ravages and is yet dreaded, but further on Mr. Rice contradicts himself, for we read :—" The borer is, however, no longer the dreaded enemy to the insidious ravages of which the planter has helplessly to resign himself. Its destructive progress has not only greatly subsided, but experience has taught the planter by vigorous and timely measures, to keep it down to a minimum." Setting aside Mr. Rice's inconsistency, there is no use disguising the fact that the borer exists in Coorg, and is as much to be dreaded as ever. We agree with the writer, however, in urging the planters not to give way to despair. The use of artificial manures and increase of shade will probably keep off the dreaded foe. As to seasons, the new instructions issued by Government for conserving the forests in Coorg will, doubtless, in the course of a few years, increase the rainfall in the district. From the figures furnished by Mr. Rice, it is evident that the export of coffee from Coorg has been falling off considerably of late years. In 1872-73 the export was 6,497 tons ; in 1873-74 it fell to 4,887 tons ; and in 1874-75, to 4,234 tons. The total number of estates in Coorg is 4,235, covering an area of 106,759 acres, and yielding an assessment of Rs. 96,241. About 50,000 acres of the whole area are held by Europeans. It seems probable that coffee culture was introduced into Coorg about the same time as into Mysore. Mr. Fowler was the first European planter in Coorg ; he opened out an estate in Mercara in 1854. Mr. H. Mann, Dr. Maxwell, and others, soon followed, and the climate of Coorg being such a genial, healthy one, coffee-culture in that Province attracted numbers of Europeans. To the great rush which was made to Coorg, may be traced, we are of opinion the commencement of bad seasons, and the advent of the borer. Several of the immigrants were Ceylon planters, who had not learnt to value shade. The evil example spread ; the jungle was ruthlessly felled, and, in consequence, the rain-fall soon decreased, and the borer, driven from his native habitat, to the bamboo, took to the coffee tree. It is only time and patience which can remedy these evils.

THE PERAK COUNTRY.

THE last mail from Singapore brought advices from Mr. Forres Lawrie, regarding the Perak country, and its supposed suitability as a field for European enterprise. The letter received from this gentleman enclosed a sample of coffee taken from a Malay garden 1,800 feet above sea-level. The bean is well-formed, though not large, and of a rather dark and dull color, somewhat resembling Natal coffee. The writer of the letter in question does not appear to have formed such a favourable opinion of the country as Messrs. Christie and Handyside entertain, and he says, that although there are navigable rivers which enable a traveller to obtain access to the high lands suitable for cultivation, the tedious boat journey of three days and three nights, was in his opinion, a great drawback, as in the event of floods there might be a risk of being cut off from communication with the coast settlements, and thus incur risk of having a large labor force starved out. For this and other reasons, Mr. Lawrie would be induced to give the preference to the low country where there is an abundance of good soil suitable for tropical produce of all kinds, and where the climate is favourable for health. As regards this part of the country, the writer, says, he will be prepared to furnish a full detailed report of the localities he has visited touching soil, climate, capacity, cost of production, &c., &c., if he can find twelve persons sufficiently interested in the matter to subscribe Rs. 100 each for the results of his experience and opinions.

THE COIMBATORE COFFEE WORKS.

ONE of the largest Coffee Curing Establishments in Southern India is at Coimbatore. The Firm of Messrs. Stanes and Co. commenced business in 1861, and has had a most prosperous career since. At the present time it cures and ships 1,500 tons of coffee annually, and numbers among its constituents almost the entire body of Neilgherry planters, European and Native. With the growth of the business, Messrs. Stanes and Co's premises have increased. They are replete with every convenience, and machinery is largely employed. The amiable head of the firm, Mr. Robert Stanes, will readily permit an inspection of the various buildings by any one desirous of making himself acquainted with the processes through which our coffee passes before it is fit to be placed in the Home market. We, however, proceed to describe these works for the benefit of those who cannot make a personal inspection. In a line with Messrs. Stanes and Co.'s office, is a series of godowns, into which the crop of each estate is received as delivered, and preliminary to exposure on the barbacues to be dried. On the arrival of a consignment, a careful comparison between the invoice and the delivery is instituted by a responsible officer of the works in the presence of the man who goes in charge, who, after measurement, obtains a receipt for the quantity delivered. When dried, the parchment coffee is conveyed in bags to two circular peelers, worked by a stationary engine. These peelers are fed at the rate of about eight bushels each, per every three minutes, and between them deliver from sixteen to twenty tons of peeled coffee per diem. The husk, which ultimately goes to feed the engine is removed by a winnowing machine adjacent, after which the coffee is emptied into a rough sizer. From the sizer it is carried up an inclined plane to a spacious upper-storied room, in which from 200 to 600 women and children, seated at dwarf tables, are busily employed picking out the broken coffee. The people are paid from a few pice to about two annas and a half, according to age and experience, per diem, and some of them have been employed upon the works ever since they were established. It was interesting to learn that girls who accompanied their parents to the works, fifteen or sixteen years ago, were now themselves mothers, and led their infants in like manner at the present day. On the same floor with these people is the final sizer, which delivers in the lower story, in five assortments, classed A., AA., B., C. and Peaberry. The coffee is here packed in cases, and is ready for shipment. The arrangements for storage and safe custody, seem to be as satisfactory as it is possible to make them, and are well calculated to guard against theft or misappropriation. A European patrols the premises during the night, and the people employed upon the works are every evening challenged by a European porter and, if necessary, searched by a female attendant. A couple of watch dogs are now on their way out intended for this firm, and on the arrival of the dogs, the property of its constituents will be as safe as the firm can possibly make it. The experience of the past year has shown that the natural shrinkage of the coffee on exposure on the barbacues at Coimbatore has given rise to some doubts as to the efficiency of arrangements for the safe custody of crop sent to the works to be cleaned, and some recriminatory correspondence has been the result, but it will be seen from what we have said that Messrs. Stanes and Co, do their best for their constituents in this respect, and that the

discrepancies in measurement are the result of natural causes. Other curing agencies have had a similar experience. So unfavorable was the weather last year, during crop time, that one planter told us he was obliged to despatch to Coimbatore from five to six tons of parchment per day taken directly from the vats. It was, of course, impossible for these consignments to be the same in bulk when dried as when delivered in a reeking state.—*South of India Observer.*

SERICULTURE.

NEWS comes from Japan that the silkworm season has been a very disastrous one for the growers.

SERICULTURE is rapidly progressing in the Southern States of America. Only three years ago Mr. Samuel Lowery, a coloured lawyer of Huntsville, commenced the raising of silk worms, which proved very healthy. Mr. Lowery has now a number of mulberry trees planted, and will have for sale this spring from 4,000,000 to 5,000,000 of eggs, worth about \$6·50 per ounce, or \$1 per 100. He thinks that the cost per acre of silk culture would be about the same as that of cotton, and estimates the product as from 150 to 200 lbs. of silk per acre, worth from \$4 to 6 per lb.

THE exports of chussum (waste silk) from Calcutta since the commencement of the official year 1876-77 have been as follow :—

			Quantity LBS.	Value RS.
1876-77	To Foreign Ports	...	659,755	417,692
	„ Coast Ports	...	78,518	71,626
1877-78	To Foreign Ports	...	822,640	604,876
	„ Coast Ports	...	46,116	36,673
April to Sep. 1878.	To Foreign Ports	...	399,948	306,017
	„ Coast Ports	...	22,144	15,360

The exports of all raw silk including chussum were—

1876-77	To Foreign Ports	...	1,410,372	77,48,843
	„ Coast Ports	...	372,091	17,61,351
1877-78	To Foreign Ports	...	1,491,950	70,20,331
	„ Coast Ports	...	634,888	41,93,852
April to Sep. 1878.	To Foreign Ports	...	690,386	71,04,547
	„ Coast Ports	...	247,790	14,12,296

The difference between the value of ordinary raw silk and chussum is so great that, having regard to the extent of the trade in the latter article, it is possible that wrong inferences may be drawn from the figures in the trade returns where the exports are added together, undistinguished, under the head of Raw Silk. The Governor-General in Council has accordingly directed that in future, chussum and cocoons shall be shown separately in the returns of the sea-borne trade.

THE WILD SILK INDUSTRY OF INDIA.

TUSSER silk has long been known and used by the natives of India. They have exported it in considerable quantities of late years, but from their imperfect mode of manipulating it in its earlier stages of manufacture, and from the difficulty of dyeing it well, it has made but little way in Europe except for ladies' and children's dresses in an undyed state. In Bengal and the adjoining provinces from time immemorial the natives have manufactured this silk into cloth called "Tussor dhooties," which is worn by Brahmins and other sects of Hindoos. In 1858, Dr. Birdwood brought the wild worms under the notice of this country, and urged their utilization. The silk is found from the north-west range of the Himalaya, south as far as Midnapore, in Bengal, and through the north-east range to Assam, and southward to Chittagong, and probably further. It is found also in the Presidencies of Bombay and Madras, and is said to be abundant in Bhagulpore in Bengal. It abounds chiefly in the eastern districts of Chattisgarh, namely, Raipore, Bilaspore and Sambulpore, in the Chanda district of the Nagpore province, and the Leono district. The natural colour of the silk is a darkish shade of fawn, much unlike the golden and white colours of the mulberry-worm silks. It has much less affinity for dye stuffs, especially for those which grow in India, and it has not until recently been much dyed. For several years I have been engaged with considerable success in improving the methods of dyeing, and the results are shown in a case at the Paris Exhibition. These improvements in the manufacture and dyeing are likely to have a very great influence on the cultivation of this silk, and probably also of other wild silks, the demand for which may in a few years be only measured by the quantity which can be produced. The larvæ of the Tusser, when fully grown, are about four inches in length; they have twelve joints or articulations, besides their extremities. Their colour is green, resembling the leaves on which they feed; and they are marked with reddish spots and a reddish yellow band running lengthways. They feed on several plants :—

Rhizophora calceolaria. Linn.
Terminalia alata glabra (Assum tree).
Terminalia tomentosa (the Saj tree).
Terminalia Catappa (Country Almond tree).
Tectona grandis. (Teak tree.)
Zizyphus jujuba, (Ber tree.)
Shorea robusta. (Sal tree.)
Bombax heptaphyllum. (Semul.)
Careya sphærica.
Pentaptera tomentosa.
Pentaptera glabra.
Ricinus communis (Castor oil plant).
Cassia lanceolata.

In six weeks from the time they are hatched they begin to spin their cocoons, which they most curiously suspend from the branches of the trees by constructing a thick hard cord or filament of silky matter, which is made to grasp the branches. As soon as the worm has spun its cocoon it takes the form of chrysalis or pupa, and remains a prisoner in the cocoons for about nine months, or from October until July. At the end of this time the chrysalis assumes the form of a moth, and whilst its wings are in an imperfectly developed state it softens one end of the cocoons with an exudation which enables it to separate the filaments of silk and to work its way out of the cocoon. This it effects during the night. The weight of the ordinary Tusser cocoon, with its pupa enclosed and the cord by which it is attached to the branch, is about five grammes. The Tussur moths are known under the following names :—

Antheraea Paphia (Linnæus).
Bombyx „ (Hübner).
Saturnia „ (Helfer).
Phalæna Attacus Mylitta (Drury).
„ Paphia (Roxburgh).
Bombyx Mylitta (Fabricius).
"Bughy" of the native of Burbhoon Hills where the silk (which the same people call "Tusseh") is manufactured.

The male is of a reddish pale brown colour, and the female much yellower. Mr. O'Neil in his report says :—"The moths are particularly revered by the people engaged in the culture of the worms, the occulili on their wing being considered as the 'chakra' or mark of Vishnu. These people also pretend to observe the greatest purity of life during the time they are in the jungles rearing the worms, and do not eat flesh, fish or spices, do not shave or cut their hair, do not wear washed clothing, nor anoint their bodies with oil, and do not touch any person of whom a relative may have recently died." Organzine and Tram Tusser are shown of the quality and state of manufacture now used in England for weaving, and a good representation of the present state of its manufacture which gives a size of 255 deniers (15 drams per 1,000 yards). The sizes of the Tusser silk generally used in England run from 152 deniers (9 drams) to 255 deniers (15 drams). These are very coarse sizes and must necessarily be unfit to produce such fine textile work as the mulberry silk which is manufactured into Organzine and Tram of 21 deniers and upwards ($1\frac{1}{4}$ drams) and from which are made the finest silk fabrics. The want of fineness and quality is owing to the imperfect and unskilful mode of manipulating it from the cocoon upwards in India, and the want of better machinery to prepare it in the raw state. The improvement in quality, fineness, and cleanness in the Organzine Tusser manufactured, &c., under my own instructions and superintendence will be seen to be most marked; instead of the coarse sizes of Tusser now used, of 152 to 255 deniers (9 to 15 drams), there may be obtained by proper management, Organzine and Tram of excellent quality from the same cocoons of 51 deniers (3 drams) and upwards, which can be woven into a great variety of stuffs, for which until now only the mulberry silks have been available. The attention of all interested in or connected with silk manufacture, cannot be too strongly drawn to this fact, nor its value be overrated. There is a most important future in store for the Tusser silk industry, and as great improvements will take place as those which resulted from the introduction of proper machinery

and skill many years ago, in the mulberry silk districts of Bengal, when it was found that Bengal silks, in place of being almost unworkable, could be manufactured in such a way as to bring them into extended use in Europe, so as even to rival French and Italian silks. The cost of making Organzine and Tram from the cocoons by the improved mode is about 20 francs per kilogramme. Mr. Neil, in his report (1875), says :—"The native contrivances for manufacturing silk are very simple, but improvement is required in the art of manufacturing silk fabrics." Now printed Tusser silk can be successfully used for wall damasks, curtains, furniture coverings, hangings, women's and girl's dresses, with great effect, and I would draw the attention of upholsterers and broad silk manufacturers to the specimens shown. The silk fabrics made of Tusser are very strong, most durable, and possess much lusture. The patterns printed in blue are the first successful application of indigo on silk as a print, and not as a pencil blue. They will prove remarkably fast, in fact none of the colours are printed in aniline or any other fugitive dyes. Notice the rich tone of blue they bear, modified to some extent by the ground colour which has controlled too great a brightness. The *Attacus Cynthia*, a wild silk-worm of India, produces the silk known as Eri or Eria of Assam.

It is also known under the following names :—

Phalæna Cynthia (Roxburgh).
Bombyx Cynthia (Olivier).
Samia Cynthia (Hubner).
Saturnia Cynthia (Westwood).
Saturnia Arrundi (Royle).
The Arrindi or Arrundi silk-worm moth (Roxburgh).

With this I must connect the *Attacus Ricini* (Boisduval), the same insect so far as I can gather, except that it is fed on the *Ricinus Communis*, or Castor Oil plant, and is reared in a domesticated state in Assam, and over a great part of Hindustan, more especially in the districts of Dinagepore and Rungpore. Mr. Hugon gives the following interesting particulars respecting it : "The larva when at full size is about $3\frac{1}{2}$ inches long. It spins its cocoon in four days. The hill tribes settled in the plains are fond of eating the chrysalis." The cocoon is much smaller than that of the Tusser and is soft. The natives cannot wind the silk, but spin it like cotton Dr. Helfer says the insect is so productive as to give sometimes twelve broods a year, and that the worm grows rapidly and offers no difficulty whatever for an extensive speculation. Mr. Atkinson says the filament is so delicate as to render it impracticable to wind off the silk ; it is therefore spun like cotton. The yarn thus manufactured is woven into a coarse kind of white cloth, of a seemingly loose texture, but of incredible durability, the life of one person being seldom sufficient to wear out a garment made of it. The winding of the Eria cocoon is said to have been recently accomplished ; the thickness of the Eria filament is $\frac{1}{1500}$ of an inch. Leaving the question as to whether it can be successfully wound or not, one important consideration respecting its use presents itself, namely its capability of being spun like cotton and wool. The great improvements made in late years in England in spinning machinery have proved that marvellous results in making an even thread from waste silk and unwindable cocoons, for sewing and weaving purposes, may be attained, and I will venture to predict a future for this and the produce of all unwindable silk-worm cocoons that will compensate for their collection. The industry of the natives should be stimulated to the gathering in of all kinds of wild silk cocoons, whether windable or not, for there is no doubt that those kinds which cannot be wound can be most easily spun, and there is at the present moment a demand on the part of silk spinners for a larger supply of Tusser silk cocoons and Tusser silk waste for spinning purposes, and no doubt other silk cocoons would be gladly bought up.—*Thomas Wardle, F.C.S., F.G.S., Leek.*

THE ROYAL BERKSHIRE ROOT SHOW.

On Saturday some 17,000 persons visited the seed stores of Messrs. Sutton and Sons, at Reading, to view the 29th annual show of roots grown by customers of the firm in almost every county in England and Wales and also in Scotland. Among the company were Viscount Eversley. Colonel Loyd-Lindsay, V.C., M. P, Mr. Walter, M.P., Mr. P. Wroughton, M.P., Mr. J Shaw-Lefevere, M.P., the High Sheriffs of Berkshire, Oxfordshire, and Buckinghamshire, and M. Alfred Dudoiy, Commissioner from the Société des Agriculteurs de France.

Nearly 1,600 entries were in competition for the prizes, amounting to £300, including specimens contributed by the Queen, the Prince of Wales, the Dukes of Northumberland and Portland, the Marquises of Donegal and Ailesbury ; the Earls of Craven, Warwick, Redesdale, Northbrook, and Bathurst ; Lords Calthorpe, Camoys, Chesham, Eversley, Keir, Moreton ; the Countess of Yarborough, Sir W. Heathcote, Sir G. A. C. East, Sir C. M. Lampson, Sir C. Russell, M. P., V. C., Sir Paul Hunter, Sir C. F. Smythe, Colonel Lloyd-Lindsay, V. C., M. P., Mr. Walter, M. P., and the Right Hon. W. H. Smith, M. P. As a result of a careful inspection, we may say that the extraordinary feature in the Show is the absence of any commonplace specimens throughout the whole of the classes, while the general standard of weight and quality, particularly in the classes of mangels, white fleshed turnips, and parsnips, has never been equalled at any other exhibition. The mangels occupied the floor of the main room, which is spacious enough to seat 5,000 people, and the judges had great difficulty in deciding the principal prizes, so close and meritorious was the competition.

The heaviest mammoth long red mangel weighs 47lb, and measures 3ft. in length ; the heaviest yellow glove weighs 38lb., the heaviest golden tankard 39lb., and others in equally remarkable proportions. The champion prize, and gold cup value £20, for the best 36 mangels is taken by Sir Paul Hunter, of Mortimer-hill, whose roots are of the following remarkable weights :—Twelve mammoth long red 406lb., twelve golden tankard 379lb., twelve yellow globe 315lb. One of the most remarkable exhibits is a collection of several hundred roots grown on Reading Sewage Farm this year, and drawn from a crop of 50 acres. Finer specimens have seldom been seen, and the whole crop is the heaviest field crop on record, as the following weights will show :—Sutton's mammoth long red, 119 tons per acre, on seven acres ; Sutton's golden tankard, 88 tons per acre ; Sutton's Berks prize yellow globe, 77 tons per acre ; and Sutton's yellow intermediate, 77 tons per acre.

Cabbages are shown weighing over 56lb. each, and a gourd attaining the enormous weight of 162lb. The winners of the chief honours were, for mangels, Sir Paul Hunter, Mr. R. Burn-Blyth, Sir F. Smythe, Mr. Richard Webb, Messrs. J. and W. H. Clarke, and Sir Richard F. Sutton ; for swedes and turnips, Mr. J F. Burroll, Mr. H. Middleton. Mr. J. S. Calvert, Colonel Loyd-Lindsay, V. C., M. P., Mr. W. Willis, Mr. Charles Keep, Mr. W. Hobbis, Mr. J. Bramstone Stone, Mr. J. H. G. Love, Mr. H. Palmer, Sir Curtis Lampson, Mr. R. Lees, and Mr. W. Townsend ; for kohl rabi, Mr. W. Beale, and Mr. Thomas Aitken ; for cabbages, Mr. S. Robinson and Sir Paul Hunter ; for white carrots, Sir Paul Hunter and the Hon. Mrs. Hay. Among the collections of potatoes the most superb show is that of Sutton's Magnum Bonum variety.

The judges were—Mr. J. Brebner, her Majesty's Norfolk Farm, Windsor : Mr. W. Brignshaw, her Majesty's Bagshot Park Farm ; Mr. James Buckman, Professor of Agriculture ; Mr. J. Chalmers Morton ; Mr. H. Simmons, Bearwood Park Farm, Berks ; and Mr. H. Tait, her Majesty's Shaw Farm, Windsor—for roots ; Mr. C. Penny, gardener to the Prince of Wales, Sandringham ; Mr. J. Tegg, gardener to Mr. Walter, M. P., Bearwood ; and Mr. Coombes, gardener to Mr. R. Benyon—for potatoes and vegetables.—*Times*, November 25th.

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah *in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.*

LETTERS TO THE EDITOR.

TUSSUR SILK.

TO THE EDITOR.

SIR,—Silk is an article that well deserves the attention of governments, land owners, manufacturers and commercial men. I purpose proving this upon authentic data, and at the same time of shewing clearly a special source of wealth in connection with it that India alone possesses.

Whether from the more general consumption of those products that indicate and follow the standard of civilization amongst the middle classes, or owing to the repeated blights of the mulberry tree, there has been in Europe during the past 50 years an increasing disposition to resort to foreign sources of silk supply to replace the home consumption. Asia, especially China, Japan, and India, has been the most turned to account to satisfy the European demand The Tussur, however, is one amongst the many kinds of cocoons, that it would be well to study as the possible and sound substitute for those of the mulberry tree—conforming as it does in some of its special characteristics. It is bright and elastic, while its strength of tissue admits of the thread being diminished in the winding off, without losing any of the qualities required by the dyer and the loomsman. The better to acquaint my reader with the production and consumption of silk throughout the world, I submit for his consideration a table compiled from the statistics of the Italian Government

Produce throughout the world of the different silks from the mulberry tree cocoons.

		Nations.	Kilogrammes.	Total	European consumption	REMARKS.
	Kilos	China	7,500,000	Asia ..	3,000,000	Accepting the statistics of Mr Richter the production of Italy would be 4 millions, others shew the yield to be 3 millions only, but the Italian Government acknowledges to 3,600,000
Of the rough silk of China there are		India .	2,000,000		500,000	
	3,000,000	Japan ..	2,000,000		700,000	
and of the tussur silk of India .		Russia .	1,000,000		400,000	
	2,000,000	Turkey .	400,000		350,000	
				12,900,000	4,850,000	
		Italy .	3,600,000			The mooga and tussur silks are not manufactured in Europe.
		France .	600,000			
		Austria	250,000			
		Spain and Portugal	150,000			
		Greece, European Turkey, &c., &c.	100,000	4,700,000	4,700,000	
Total .	5,000,000	Grand Total	. .	17,600,000	9,550,000	

N B—The average prices of Asiatic and European silks during 10 years have been respectively 50 and 65 *francs* the *kilo*. Thus the

4,850,000	Asiatic ..	@ 50 *f.*	=	242,500,000 *francs.*
4,700,000	European	.. 65 *f*	=	305,500,000 ..
Kilos ... 9,550,000			*Francs*	548,000,000

Italy does not manufacture in proportion to her large production Thus one finds that the number and distribution of the silk factories throughout Europe are as follows:—

In France		120,000
" England		120,000
" Germany	70,000	120,000
" Switzerland ...	40,000	
" Austria	10,000	
" Italy		12,000
Total of European factories ...		372,000

Italy holds in Europe the first place as producer; having no less than 4,805 factories at work upon her own productions (4,355 *à feu* and 450 *à vapeur*); while France has not more than about 900 factories devoted to the same purpose, of which the greater number are each fitted with 100 dimity looms (*basines*). But besides the silk from cocoons nurtured at home, she uses a vast quantity supplied from abroad. In the manufacture of silk dress materials and lace there is used of

Indigenous produce	30	per cent. of the total outturn.
Of Italian	22	" "
Of Asiatic	48	" "
	100	

To assure oneself that the use of silk is becoming more general among the middle classes and decreasing among the upper, it can be necessary only to consider the following table, showing the proportionate distribution of silk manufactures in France at different periods.

Sales effected during the years ...	1855.	1862.	1871.	1872.
The value of heavy priced goods in millions of francs was ...	39	30	9	14
The value of low priced goods in millions of francs was ...	142	193	294	308

In addition to these figures I will give the quantities exported, as shown by the French Custom House returns at various dates.

From 1827 to 1836	in millions of francs ...	121
" 1837 " 1846	" ...	134
" 1817 " 1856	" ...	274
" 1857 " 1866	" ...	414
" 1867 " 1876	" ...	465

And still further to shew the changes undergone in France in the progress of this industry I give a table of the factories that have been at work during the past 200 years.

In 1684 ...	10,000	In 1823 ...	21,000
" 1705 ...	2,000	" 1827 ...	27,000
" 1788 ...	18,000	" 1831 ...	42,000
" 1793 ...	3,500	" 1848 ...	50,000
" 1810 } 1815 } ...	12,000	" 1852 ...	65,000
		" 1864 ...	120,000

To sum up, there can be no doubt of the almost boundless consumption of silks of every kind, but, above all, of those that go specially to the manufacture of the materials that savour of democracy. Having formed an idea of the nearly limitless extent of the total quantity of silk used, I invite the reader to think of the wealth that India might possess, would she but increase the production of tussur cocoons. If the industry were left altogether in native hands the result could only be applied to the manufacture of the course material known as tussur cloth. The present outturn would in that case be enough; the two harvests that fall within the year would sometimes even more than supply the demand. But since we have found the means of winding off the tussur silk as finely as that from the cocoon of the mulberry tree itself, it seems to me wrong that this natural resource should be neglected. Government, in the first place, and the land owners, in the second, should encourage its nurture—nature would repay the encouragement manifold. The tea and jute enterprises have proved the wisdom of leaving in native hands the growth of natural produce—with the help only of the needful European capital and supervision. So far as Government is concerned, it might cultivate the tussur cocoons by the system now applying to opium, but with a tenth of the trouble. Consider for a moment the multitude of trees to be found amidst the jungle that will nourish the tussur silk-worm. Oaks of all kinds—Terminalia pentaptera tormentosa, Zizyphus jujuba, Ficus binnaminas, Ficus religiosa, Carissa, Grudia, Wrightia, Terminalia catappa, Terminalia alata, Bombax hopthaphyllum, Shorea robusta, Carea sphacria, Hagerstiauvia carviflora, Canocarpus latifolia, Pentaptera Arjuna, Syzyguim jambutanum, Tectora grandis. I will not dwell upon the simple treatment needed by the silkworm while in the tree, that supplies it, with all necessary nutriment. Almost all it needs is that the birds shall be kept away during the 35 days that constitute its life. The cocoon is completely formed in 8 days, and all who have experimented on its cultivation have proved that the cost of fresh materials of production would not be more than 14 to 15 annas per 1,000 cocoons. Say a rupee, however, yet it must always be satisfactory to produce for one what may be sold for four rupees. The latter price is the one commonly accepted for the small supply of silk yet produced, but it might be realized for all that India could produce—would she but encourage the industry. It must be seen at a glance that the cultivation would become no less valuable than that of opium, and that it could be adapted without difficulty to the jungles of India.

If more extended information be wanted regarding either the nurture and treatment of cocoons or the mode of preparing them for the market I shall be happy to furnish it; or to render any other assistance that may be in my power.

F. L.

MODEL FARMING.

SIR,—I have been recently perusing some amusing articles on the attempts made in various parts of India in model farming; they all seem to be intended to teach the native ornamental gardening or high farming. For many years any such attempts must be failures. For anything to be taught must be begun in its elements before higher things are attempted; and what is required is to demonstrate to the native mind that 100 acres worked by paid labor and better ploughing would be more profitable than 10 acres worked by his own labor; and that certain crops yield a better return than inferior ones. Now the staple produce of India is wheat and rice. The production of the first in greater quantities should be encouraged, and rice, as now planted, is broadcast and re-planted, costing great labor. An attempt might be made to introduce Carolina rice. With the hoe it can be planted at once, as it is planted in ridges and needs less watering than the Indian rice, and does not require transplanting. And secondly, the natives should be taught the use of the American plough, with which some experiments have been made at the Central Jail, Calcutta, with great success: it seems to be well adapted for India, and costs a moderate sum. The great defect of the Indian plough is that the ground has to be gone over five and six times before it is fit for use; and the introduction of a better kind of harrow is required. What model farms should aim at is to show the natives the advantage of better tools, and the most remunerative crops. Of course inferior crops will be raised, as they form the staple food of the natives; but if they could get wheat or rice cheaper they would prefer them.

PHILO.

Calcutta, 23rd February, 1878.

DE OMNIBUS.

SIR,—The weather during the past month has been unusually dry, in fact to such an extent has this been the case, that I much doubt whether we shall obtain more than a three-quarters crop of cereals. Although if this dry weather continues, there is no doubt but that this proportion will be further lessened. This does not mean a famine, (though I dare say the local officials would like to have a famine for the grist it brings to such gentry) as the people have sufficient to tide them over until harvest time, though it does mean a temporary tightness in the price of food grains. If Providence is merciful and sends "such moderate rain and showers that we may receive the fruits of the earth to our comfort, and his honor," the rainy season crops ought to be bumper ones, as the ground will have had a slight rest and double ploughings which will have given it a large supply of light and air.

Subjoined is an abstract of some meteorological observations kept during the past five years.

JANUARY.

	1875.	1876.	1877.	1878.	1879.
Snowy days ...	2	2	5	3	1
Haily " ...	—	—	—	—	—
Rainy " ...	—	4	4	2	—
	Dry.	Dry and warm.	About 31 inches of snow.	Suitable	Excessively dry only about ¼ of an inch of snow.

The wind is generally from western quarters bringing up the vapours, which fall either in snow or rain.

Themometer (Fht.) hung in open verandah about 39 at 7 A.M., and 50 at 6 P.M.

Grass and jungle burning—those curses of the country—progressing with the usual vigour, thus burning up seedlings and keeping the sides

of the mountains quite bare of arborescent vegetation. The present drought may be in great measure laid to this sinful proceeding. It is simply a sign that the graziers have too large an area of grazing ground as grass-land, properly fed down or harvested, needs no firing, and what is more to the point new grass will spring up much quicker where the two former operations have been carried out than on the latter. *Verb. sap.*

Owing to the dryness of the season the cotonifolium fœteus, apple and cherry trees have not yet come into blossom. The buds of many trees, such as the willow, peach, walnut; rhododendron are now swelling. Should they come out too early and cold sharp windy weather set in afterwards, great loss will be the result. The chekul (*Prinsepia utilis*) with its wee white flower, the wild oleander (*Nerium oleander*) with its white wax-like, (though so pretty, nearly every part is poisonous) are our principal flowering shrubs: of wild flowers we have a few cistus with their yellow petals, violets (scentless at low elevations and in exposed situations) and buttercups in sheltered and moist situations, there are a few ferns.

The sportsman can now obtain stags (*ral nembu*); musk deer (*kastúra bina*); barking deer (*khakkar*); chamois (*gural pif*) hare (*khargos*) porcupine (*shahai*) wild pig (*jungli sür*) bear (*balu rikh*) leopard (*bragh*) flying squirrels (*iin*) hill fox, pine marten, lynx, jungle-cat, wood otter, jackel, most of these require careful stalking, and for the sportsman to keep in the neighborhood of the snow just below which point most of the animals birds also, live or come down to, in order to obtain food, others are found about the fields and ravines; the bears can be killed in their dens with proper precautions.

Of birds we have pheasants, the argus (*thahi*) manaul (*minal*) long-tailed (*chir*); chockolate breasted (*kohlas plach*) silver breasted (*khallege*) partridges, olive (*bantitr*) black (*titr*); chakore (*chikor*); quail (*batere*) woodcock; pigeons, green, large blue, winter white breasted, and mottled breasted; all now in full winter, plumage. While down by the bank of the river there are the wild goose (*jungli raj haus*) wild duck and teal. Fish, the mahsir and a small kind of trout are caught in the river.

The crops now growing are wheat and barley.

Price of wheat 10 seers for the rupee.

Gardening operations confined to carrying out manure, transplanting fruit and other trees, digging and preparing ground. Mignonette, naricissus, red, pink, and white roses, petunia now in blossom; among vegetables are cabbages, turnips, carrots.

G. P. P.

Koteghur, 1st February 1879.

MR. ROUTLEDGE ON BAMBOO.

(*To the Editor of the Englishman.*)

SIR,—In your paper of 21st January, you printed a letter from Mr. Thomas Routledge, in which he comments on the ill-success of the experiment in cropping bamboos described in the report of the Botanic Garden for 1877-78. Mr. Routledge attributes the failure to my having followed a faulty system with the invention of which he appears desirous of crediting me. Now nobody can have a poorer opinion of the merits of the system which was followed in this experiment than I myself have.

The system is not, however, of my invention, but was suggested in a pamphlet entitled "Bamboo considered as a paper-making material," published during 1875, by no other than Mr. Routledge himself.

In his letter to you Mr. Routledge objects very strongly to the cutting of all the shoots of each clump of bamboo, and says my results were bad because I did this. In his pamphlet just named, Mr. Routledge described his scheme of growing and cropping bamboos in the following words:—

"The stems of the 'bamboo,' cut young, as I propose to use them, contain from 60 to 75 per cent. of moisture; it will be obvious, therefore, that to ensure a regular and continuous supply under economical conditions, to a central factory for the manufacture of 'paper-stock,' plantations would have to be formed contiguous thereto, as practised with 'sugarcane,' or in a similar manner to osier beds in England.

* * * * * * *

"With plantations of 'sugarcane,' to which plant the 'bamboo' somewhat assimilates in character and growth, it is necessary, in order to ripen the canes and develop saccharine, to allow free ventilation to the growing plant, and thus the ground is not fully occupied. This would not be the case with 'bamboo,' which should be planted and grown closely together to favor the stems shooting upwards, as practised with 'hemp' and 'flax,' where fine staple of fibre is desired.

"By following such a system, the stools or roots once established, a systematical and regular cropping, or cutting, would ensue, the stems being all cut down simultaneously, by sections or beds, in regular succession, numerous croppings annually would thus be obtained, and, when necessary, fresh beds would be formed, the older growth being avliable for fuel for the manufactory.

"The sugarcane from the time of planting to cutting takes from nine to twelve months to grow and mature; but even thus grown, the produce of canes (ready dressed for the mill) generally ranges from 30 to 35 tons to the acre; it sometimes exceeds 40 tons; allowing several crops and cuttings annually for the 'bamboo,' it may fairly be assumed that at least this latter quantity would be obtained per acre.

"Allowing 208 feet square to represent one acre, divided into twelve beds, each 96 by 26 feet, with twelve paths 96 feet, 8 feet 8 inches wide, and one intersecting road 208 by 16 feet wide, leaves a space for planting equal to 2,496 feet, or 29,952 feet in the twelve beds; allowing the stems to be 2 feet apart, and say only 12 feet high, we have 7,488 stems, which at 12 lbs. each. equals 40 tons per acre."

It appears to me impossible to understand anything from this extract, but that the writer of it intended all the shoots of each clump to be cut, inasmuch as in his calculation of the annual outturn of an acre he includes the weight of every stem grown on that acre.

The plan of cropping thus proposed has always seemed to be perfectly Utopian, and I have expressed my opinion of it freely enough in more places than one. For example in a paragraph of the report of the Botanic Garden, in which the experiments were described I wrote as follows:—

"Mr. Routledge's expectations imply a very complete change of habit in the bamboo; for it is pretty well known that bamboo clumps, entirely cut down, yield for several years but few and small succulent shoots, and in fact not unfrequently die."

However, as Mr. Routledge's project for cultivating bamboo in the way described in his pamphlet was being pressed with some persistence on Government, I felt bound to put it to the test of actual experience. I did so with results that have so vexed Mr. Routledge that he now tries to throw the discredit of them upon me. I am quite ready to accept Mr. Routledge as an authority on the probable value of young shoots of bamboo as a paper fibre, and to admit that paper stock derived from them may one day become an article of export from India. But I hardly think the latter result is likely to be any the sooner brought about by attempts to deny the paternity of an inappropriate scheme so soon as its inappropriateness shall have been practically demonstrated.

The plan of cropping which I understand Mr. Routledge now to recommend is that only a few of the young shoots be taken from a bamboo clump each season, and that the other shoots, both young and old, be left uncut. So far as the plants are concerned there would be no objection to this system. But I fail to see how it could be carried on to a profit in this part of India. According to Mr. Routledge, five shillings per ton is the price which could be allowed for young bamboo shoots delivered at a paper stock factory. No doubt bamboo grows in enormous quantities in remote districts where it could be had for little more than the cost of collection, and where there is excellent water-carriage. But, unfortunately, bamboo shoots at the stage of growth required for Mr. Routledge's process are of higher specific gravity than water, and could not be rafted without more or less expensive arrangements for floats. The cost of boat hire from these remote regions to a factory stationed in a civilized place would probably in most cases bring the raw material to far more than five shillings a ton, while cartage is out of the question. There remains Mr. Routledge's plantation scheme in its new form by which only a portion of the annual shoots are to be cut. This means irrigating, manuring, and paying rent for an area of land of which only a part of the annual yield can be cut as crop. And these are by no means trifling items in Bengal. Moreover, mature bamboo stems are marketable at considerable rates in civilized districts, and it would probably be more profitable to growers to sell their bamboos mature, than to dispose of them in their succulent stage to a paper stock factory. Lastly, in putting down the annual yield of succulent shoots at 40 tons, or even at half of that per acre, Mr. Routledge is unwisely sanguine. My own belief is that from an acre of *Bambusa Bulcooa* (one of the common species in Bengal) it would be difficult to collect annually as much as from 5 to 10 tons. I look on all proposals to bring this kind of raw material to a factory as less hopeful than the proposal to take the factory to the raw material; and if the production of paper stock from bamboo is ever to become an Indian industry, I believe it will be by fitting up floating mills and moving them about on rivers in the banks of which bamboo naturally abounds.

If Mr. Routledge would but direct his inventive powers to the problem of utilizing mature bamboo stems as a material for paper fibre, he would in my opinion be more likely to attain useful results than in continuing to propose schemes for the cultivation of a plant with the peculiar growth of which he seems to have had so little opportunity of acquainting himself. Ripe bamboo stems are the most buoyant of all forest products, and a practically unlimited supply of these could

at a low cost be floated by river from Assam, the Chittagong Hill Tracts, and other districts. I am told that in Japan and China, paper is made from mature bamboos, and, if such be the case, I suppose the same could be done in England.

GEORGE KING.

Botanic Garden, Howrah, Feb. 3, 1879

BAMBOO IN THE BOTANICAL GARDEN, CALCUTTA.

(*Remarks in the annual report for the year* 1877-78.)

THERE is, unfortunately, no controverting the fact chronicled in the Report above referred to that the experiments on bamboo, in relation to its cultivation and cropping for the proposed manufacture of "Paper-Stock," conducted by Dr. King during the past two years, have resulted in utter failure.

The causes, however, of this failure are not far to seek; indeed, the system adopted during the first year rendered such a result nearly inevitable. It is now my desire to show how, with more recent investigation of the subject and more knowledge of the habit of the plant, more favourable results may not only be looked for, but, in suitable localities and climates, and with judicious management, ensured.

At an early stage of the question, in January, 1875, when I first brought the suitability of the bamboo for the manufacture of "Paper-Stock" under the notice of the Secretary of State for India, it was suggested I should address Dr. King on the subject. This I did *in extenso*, stating what I proposed, broadly giving him my views, but, being neither horticulturist, arboriculturist, nor scientific botanist, I did not profess to lay down any hard and fast line, but confined myself to describing the condition of the bamboo stems I had found best suited for my purpose, requesting Dr. King's opinion upon certain doubtful points bearing upon the best system of propagating and cropping the bamboo, inasmuch as at that time, but little being known of the plant in England, I could only glean very scant information; of course every body knew bamboo abounded in tropical countries, but I could learn but little as to its habit, and still less as to its cultivation, if indeed it ever had been cultivated.

A month or two later I published a pamphlet * on "Bamboo considered as a Paper-making Material" printed on paper I had made, at our Works here, from bamboo stems I had received from Demerara; in it embodying my views and generally stating the manner in which I judged, from analogous herbaceous growth, plantations to supply the young stems might be formed under irrigation.

This pamphlet was extensively circulated in India, through the India Office. I also, by desire of Lord Salisbury, sent out to Calcutta a box containing a selection of samples of stems of bamboo cut at the stage of growth I had found most suitable, as well as some for comparison which were too old and woody for my purpose.

This was followed in July, 1875, by a printed Memorandum, issued by Dr. Brandis, the Inspector-General of Forests (who appended there to extracts from letters I had addressed to him), admitting the importance of, and generally treating on the leading features of the question.

In February, 1876, a second Memorandum was issued by Dr. Brandis, in which he directed attention to the main points to be determined by the experimental plantations then ordered to be established by the Government of India. From this Memorandum I extract the following :—

"A method of treatment must it possible be discovered by which a "plantation, or natural forest of bamboos, may be made to yield a "succession of complete crops of young shoots throughout the year. "Our present experience is that a large proportion of old stems is "required in a bamboo clump to produce full-sized shoots, but it may "be that different species behave differently in that respect, and that a "larger proportion of full sized young shoots may be produced by "certain species, or by covering the roots with earth, manure, or "leaves, or by plentiful watering. Under ordinary circumstances, if "bamboo clumps are cut over in the forest, *all mature stems being cut* "*down at one time, the result is a crop of slender stems.* It requires "no experiments to establish this result. * * * * The experiments "undertaken *should as much as possible be comparative.* Of a number "of clumps of the same age and species, and growing under the same "conditions, *some should be thinned lightly, others heavily, and the third* "*group should be cut over completely, leaving only a few old stems on* "*the ground.*

"Again, experiments should be made in order to determine whether "cutting bamboos at different seasons has any effect upon the production of young shoots, and whether the production of young shoots can "be stimulated by selecting the stems to be cut according to certain "principles. Irrigation, manure, and covering with a layer of moist "earth, must in all cases be employed, with the view of inducing if "possible the bamboos to form a large crop of full-sized "shoots."

Now what occurred in the experiments conducted at the Botanical Gardens, as described in the Report?

"Six clumps of *Bambusa balcooa* were cut down at the beginning of "the rains, *between the 10th and 20th June, 1876*, when the buds "of the young shoots of the season had completely formed and "were nearly ready to burst through the soil. Soon after the cutting of "the old stems these buds developed into shoots, which grew with "characteristic rapidity. These were allowed to grow until they began "to show symptoms of becoming hard, *and on 21st July they were all* "*cut down.* In the beginning of the rainy season *last year* (*1877*) the "brushwood of thin woody twigs which had been produced by each "clump *was cut off*, but amongst the twigs there were none of the soft, "succulent shoots proceeding from the underground stem which are "required for Mr. Routledge's process. The clumps have just again "(10th July 1878) *been cleared of every twig* produced by them since the "previous cutting. The result is that, just as last year, the most of the "growth consists of hard woody twigs, which proceed from the bases of "the stems cut two years ago, the total yield of materials being 120 "pounds, or an average of 20 pounds per clump."

Under such treatment, as Dr. King correctly remarks, "*the proposed* "*new industry does not present a hopeful financial aspect.*" Verily it does not.

It is to be deplored that Dr. King did not follow the plan set forth by Dr. Brandis by treating each of the several clumps on a separate and comparative system, instead of adopting the "*heroic operation*" of cutting down not only *all the stems, both old and young, but even the young twigs*, on every separate clump, this being the more surprising as Dr. King *himself remarked* in his report published for 1876: "*for it is pretty well known that bamboo clumps, if entirely* "*cut down, yield for several years but small shoots, and not unfrequently* "*die.*" It would almost appear that the system adopted was to make assurance doubly sure, and prove a foregone conclusion.

The first intimation I had of Dr. King's experiments was by the publication of his report for 1877 in the *Journal of the Society of Arts* of the 2nd November, and I commented thereon in two letters also published in the Journal of November 16th and 30th.

Having now discussed *cause* and *effect*, I will proceed to show how, under a different system of cropping and treatment, the experiments conducted by Dr. King would certainly have shown a mere favourable result, and this by quoting the opinions of well-known botanical authorities well acquainted with the habit of the bamboo.

The accepted text book on bamboo is the Monograph of the Bambusaceæ by General Munro, C. B., published in the transactions of the Linnean Society. General Munro did me the favour to reply to queries I had transmitted to him as follows, September 8th, 1876:

"I have never heard of the bamboo being cultivated for successive "cropping, but I can see no reason why a regular systematic cropping "could not be carried out.

"*Bambusa vulgaris* would in my opinion be the best species to "cultivate, as it grows very readily from cuttings, so does *Dendrocalamus* "*giganteus*, which thrives remarkably well and grows fast in Trinidad, "and would, I think, produce the best fibre; *Bambusa tulda* would "be a good species in India; *Dendrocalamus strictus* also grows fast "and is easily propagated. The ordinary bamboo very rarely seeds in "the West Indies; I only saw it once in Jamaica; it is always increased "by cuttings. I do not think these should be put in at a less distance "than five feet apart; a fair sized bamboo will produce from 10 to 20 "shoots a year in moist countries.

"With reference to cutting and cropping, I should think 6 *or 7 out* "*of 10 shoots might be cut yearly* without causing any serious harm to "the parent stool; the older stems might be cut down in their second "year and serve as fuel. I should think the stools would continue to "produce fresh stems for about 30 years, about when the plants would "be likely to come into flower, and then die."

The late Mr. Sulpis Kurz, of the Botanical Gardens, Sambulpore, whose most interesting papers, "Bamboo and its Use," were published in the *Indian Forrester*, replied to queries I addressed to him—

"Regular cropping can be made only in so far as the shoots of every "rainy season can be cut down. If all the shoots be cut down, the stock "will be impoverished and ultimately die off, hence a certain per centage, "say one-fourth, of the whole of the stool would have to be spared. "The most common way of planting bamboo by natives is by taking "shoots, or the lower piece of the balm, with a part of the rhizome, and "plant during the rains; the intervals between the cuttings being "regulated by the size of the bamboo. Twelve to fifteen feet would "be a dense growth for the larger kinds, 80 feet and upwards in height,

* Bamboo considered as a Paper-making Material, by [illegible] Routledge. E. & F. N. SPON, London, 1875.

"which throw up from 15 to 20 shoots, wh... to 10 feet is the minimum "for the smaller kinds ab... ... feet: smaller kinds are not recommend- "able."

... Parish, a botanist well-acquainted with Burma and the Tenasserim Provinces, wrote me October, 1877 :—

"The shoots should *not all* be cut every year, for if this were done the "root-stock would die—only about half the clump should be cut yearly. "The bamboo once established as a strong root-stock, you can go on "cutting annually. As to the calculation of 7,488 stems per acre (*vide* "my pamphlet, p. 8), I should think that if only half were cut, a much "greater number could be got off an acre."

Numerous other correspondents have written me to the same effect as the foregoing, chiefly, however, from the West Indies.

Sir Joseph Hooker was good enough to send me a copy of a letter addressed to him by Mr. Robert Thomson, Government botanist and superintendent of the successful cinchona plantations in Jamaica, which, with permission, I published in the *Journal of the Society of Arts*, January 4th, 1878, as also, March 1st, another letter I had received myself from Mr. Thomson, to whom I had written for more detailed information. These two letters I append to these "remarks," as also a further Report from Mr. Thomson recording his later investigations of existing growth of bamboo in Jamaica, detailing its condition after a course of severe cropping. Having sent the *Society of Arts' Journal* containing Mr. Thomson's letters, to Dr. Berthold Ribbenthrop, Conservator of Forests, British Burma, requesting his views thereon, under date, August 8th, 1878, he replied :—

"There is no doubt that in fire-protected plantations a much larger "crop can be obtained than in the open forest exposed to constantly "recurring jungle fires. The bamboo jungles near villages on the Pegu "choung prove that constant cutting does not materially affect the "reproduction, and cutting the stems down within a couple of feet "from the ground maintains a perfect unimpaired action of the roots "as may be observed on the bamboo hedges in Rangoon. At the same, "time, I cannot agree with Mr. Thomson that a bamboo plantation "may be kept up indefinitely in regard to time, at least not without "re-stocking. This has been the case with the artificial plantations of "*Dendrocalamus Brandisii* here in Burma, the original stocks of "which die after about 60 to 70 years; others would doubtless be "shorter lived. The *Dendrocalamus Brandisii* plantations in Burma "are kept up by inter-planting with new stocks. Mr. Thomson's "system is doubtless the correct one. To grow bamboo like sugar-cane, "and to replant after cutting the crop, seems to me impracticable, the "maturation of small bamboos taking at least two years, that of the "larger kinds five, six, and ten years.".

In September, 1876, instructed by Dr. Ribbenthrop, Mr. R. Whittall, Assistant Conservator, visited the Pegu forests to investigate the bamboo question, taking with him specimens of the stems similar to those I had transmitted to Calcutta, and he reported :—

"I repeatedly showed the specimens of suitable bamboo to "experienced bamboo-cutters, to decide the age at which "they had been cut. Without hesitation, and quite unanimously, "they pronounced the stems of suitable bamboo to be of "the kind called in these parts *talagu*," and to have been cut "at from six weeks to four months after sprouting—that is, to have "sprouted at the commencement of the rains; the unsuitable specimens "they equally pronounced to be ... about one year older than the "others. This in my opinion quite sets at rest the question of age, at "least for the present. Bamboos "*of the year*," then, are alone suit- "able; and bamboos of more than 12 months are too hard for the "purpose. The large majority of young bamboos seems to sprout at "the commencement of the rains and during the month of July, but "the presence of very young and tender bamboos, which is by no "means seldom noticed, shows that they sprout all through the rains.

"*One fact* I am able to state from my own observation is, that there "appears to be a far larger number of bamboos *of the year*, on those "lists of scrub bamboo jungle so often found in the vicinity of "Burman villages, which are constantly being cut and hacked about, "than in the unfrequented bamboo regions of the forest. I do not "mean to say that the more the old bamboos are removed the more "numerously do the new ones appear; but the fact nevertheless seems "to point to a free but not too heavy or exhausting cutting, giving a "larger number of new and vigorous shoots."

The following extract from a letter I received from Dr. Ribbenthrop has also an important bearing on the question :—

"All my observations regarding the growth of many species of "bamboo tend to prove that you are perfectly correct in your views, and "that by artificially irrigated plantations we can force the productive "power of bamboo stocks to a very great extent. On the Pegu choung "and the Beingdat the most luxuriant growth is found close to the "water-courses, where they are most severely cut for the bamboo trade. "The banks of the Attaran river are for upwards of 50 miles fringed "by a broad belt of large, dense-growing, but for general purposes "useless bamboos."

Major Seaton, the Conservator of Forests, for the Southern Division of Burma and the Tenasserim Provinces, has also informed, and written me to the same effect as the foregoing; and Dr. Brandis kindly sent me a report by Dr. Schlich, writing me as follows :—

"It will interest you to learn that there are about 1,800 square miles "of almost pure bamboo forest in the Arrakan division of British "Burma, within a moderate distance from the coast, and all accessible "by navigable streams. The following is the substance of Dr. Schlich's "Report" :—

"The bamboo forest covers by far the greater portion of the area of "Arrakan, extending over thousands of square miles. It is composed "of *Bambusa longispatha*, *Bambusa tulda*. All these bamboos have "flowered several years ago, and the ground is now covered with "seedlings, which makes the forest impenetrable. The writer of this "report had to travel in it for days, at the rate of half-a-mile an hour, "having four men (alternately two and-two) in front employed "in cutting a passage just wide enough for a man to pass "through. In many places this bamboo forest contains no trees at all, "but, as a rule, there are isolated trees scattered over it. The trees met "with were those of the green forest, as well as those of the dry forest, "the former, however being far more numerous. This forest is green "throughout the year, and jungle fires do not visit it except at the "time when bamboos have died."

I have quoted this last report to show the enormous abundance and prolific nature of bamboo in localities and under climatic influences suitable to its development. Mr. Thomson's letters, *especially his later Report*, singularly coincide with, and corroborate the views expressed in the foregoing extracts from other authorities, tending to prove that under judicious management there can be but little (if any) doubt that the bamboo can be produced both abundantly and economically in plantations which, once established, little or no cultivation would be required

I may add that I have been induced to publish these remarks to qualify in some degree, by the authorities I have quoted, the *somewhat premature conclusions* that otherwise might be deduced from the Calcutta Garden Report, the publication of which, as it has been disseminated officially, might be deterrent on those proposing to embark in the New Industry I am endeavouring to introduce, which I feel assured ere long will assume prominent proportions, as the difficulties and prejudices generally attaching to a new and comparatively unknown enterprise gradually disappear.

Strongly impressed with its importance, I am wishful to induce the fullest investigation of the subject, as should my views prove correct, not only will a fresh channel be created for the employment of native industry in India, but an important branch of English manufacturers be materially benefited.

THOS. ROUTLEDGE.

NOTE.—Dr. King has stated in his Reports "*that young Bamboo shoots are too heavy to float*." I may mention that Dr. Ribbenthrop has collected for me this season some thousands of *young shoots* from the jungles, *which have been rafted down to Rangoon* for crushing, (by the rolls sent out by me for Government) preparatory to being transmitted to me here for manufacture into Paper, and "Paper Stock."

The above is the preface to a pamphlet on "Bamboo and its treatment" that Mr. Routledge is now preparing for publication.—ED., *I. A.*

The Indian Agriculturist.

CALCUTTA, MARCH 1, 1879.

COFFEE LEAF DISEASE.

THE death knoll of *Hemileia vastatrix* is, we think, sounding, and this great scourge of the coffee planter has after so many years of unchecked reign, at last been firmly grappled with. We publish elsewhere a paper by Mr. D. Morris, the Assistant Director of the Royal Botanical Garden, Ceylon, which embodies the most important information that has as yet been obtained on this subject. It was during the course of experiments, carried on at the Wallaha Coffee Estate, in January 1879, that Mr. Morris with the aid of the microscope traced the fungus definitely to its first stage of existence on the coffee tree. It was generally surmised, that the fungus must be present in the growing tissues of the coffee plant in a *diffused* form, and thus produce the stains that have been observed on the bark of young stems, but it had, until now, only been detected in a definitely organised form in the cellular tissue of the coffee leaf, and it was reserved

for Mr. Morris to show how it got there. It had been shown, by experiments made a year or two ago, that if the mature, orange spores of this fungus are laid upon charcoal, kept continuously moist, they soon germinate. The spores swell up considerably into gelatinous translucent masses, and develop into filaments which grow very rapidly and become more or less branched. Under such, so to speak, artificial growth, there are no orange spores formed, but at the termination of some of the branches secondary spores are produced, in the shape of radiating, necklace-shaped, strings of small spherical bodies of uniform size, closely resembling the fructification of *Aspergallus*. At the time of the year, Mr. Morris' experiments at Wallaha Estate took place, the existence of the fungus on the coffee plant is not apparent to the naked eye, and it has been generally supposed that the spores remain dormant from, say December to March. This theory has been definitely disposed of by Mr. Morris' investigations. He found and detected by the aid of the microscope, the fine filamentous threads of *Hemeleia vastatrix* covering the stem and branches of the coffee plant, and, as their growth is very rapid, covering them, as well as the leaves, with a fine network of branching mycelium. Mr. Morris finds that at this its *first stage* of existence, the fungus has no injurious effect upon the tree, and he is undoubtedly correct in stating that such nourishment as it requires at this, filamentous stage is evidently drawn from the moist shaded atmosphere in which it grows. These filaments are so minute that they cannot be detected by the naked eye, and their extreme fineness is more vividly brought before the mind by Mr. Morris' statement, that it takes nearly 40,000 to make up an inch diameter. The fungus commences its work of destruction, when the filaments reach the leaves. The upperside of the leaf, covered with a parchment-like skin, is impermeable or nearly so, and the filaments are unable to penetrate it to any extent, but the lower side of the leaf, containing the *stomata* or open pores, through which the plant absorbs carbonic acid and exhales oxygen, offers no resistance to the entrance of the filaments, more especially during wet weather, when the stomata are wide open. Once the filaments enter the *stomata*, they branch and ramify among the intercelluary tissues of the leaf in all directions and begin to feed upon the juice of the cells. Thus the fungus begins the *second stage* of its existence.

Under the stimulating influence of the nourishment, it thus draws from the juice of the leaf, the fungus soon looses its filamentary character. The filaments instead of being long and slender and moderately branched, as they appear on the stem, branches, and on the *outside* of the leaves, assume, once they begin to feed upon the intercelluary tissue of the leaf, a thicker, more branched and coral-like appearance. The terminations of each branch may be seen in contact and often penetrating the walls of the cells, and gradually the cell contents are absorbed and taken up by the parasitic fungus.

The presence of the fungus, or rather its action becomes then apparent to the naked eye, for if the leaves are held up to the light, a number of semi-transparent dots are observed here and there, revealing the centres of attack. The fungus gradually spreads throughout the tissues of the leaves and disables them to perform the important alimentary and digestive functions, nature has assigned to them. The fungus now reaches maturity and, with this its *third and last stage of existence*. The filaments again push to the outside of the leaf and develop, each thread, a single sub-reniform, orange-coloured spore, attached obliquely to the base. These spores are innumerable and the lower side of the leaf appears, consequently, covered with an orange-coloured powder; a great many of these spores fall off, when mature, and may get blown about if there is a strong wind, but the greater number of them remain on the leaves until they are shed. The heavy, oily character of these spores, inclines Mr. Morris to believe that they are not carried far from beyond the tree on which they developed, and he refers to the *secondary spores* as the chief source and danger of disseminating the fungus over wide and distant areas. The development of the *secondary spores*, to which we have above referred, instead of that of the mature orange spores, seems to depend upon certain circumstances the chief of which probable is the want of proper food (*i.e.* the juice of the *living* leaf). Mr. Morris, therefore, and we think rightly, surmised that leaves which are covered with the filaments of the fungus, and which drop off before the fungus reaches its third stage of existence, are a source of greater danger as infection carriers, by developing an innumerable quantity of *secondary spores*, than the primary orange-colored spores. The secondary spores are so minute, and of such light construction, that they are easily carried away by the wind; and as this dropping off of leaves, before the development of the orange-coloured spores, is especially notable in abandoned estates and on coffee trees cultivated by natives, it will be necessary, if Mr. Morris' surmise is borne out, to adopt legislative measures to remove what would always remain a fertile source of continually supplying secondary spores and of infecting estates, that by measures, now in course of adoption, may succeed in getting rid of this direst of enemies to the Coffee Industry.

Mr. Morris passes on, to consider the remedies that can be adopted for stamping out the disease. Sulphur and lime, jointly or separately, are the chief substances that appear adapted for the purpose. Sulphur has before now been suggested as a possible remedy, by several scientists in Europe, but with great diffidence and hesitation, as only the dry leaves had formed the basis of their investigations and they had not been able to detect the filaments *externally*.

The discovery that the fungus in its first stage of existence is entirely external and that it, so to say, climbs up the stem and branches in search of the leaves, is important, and introduces an entirely new phase of the subject. It is, of course, at once apparent that the only chance of destroying the fungus exists during the first and *external* stage of its existence. As said before, it can *then* not be detected by the naked eye, and it is necessary therefore to treat all parts of a coffee estate alike, if it is resolved to battle the enemy.

There are a great number of substances that will destroy fungoid parasites on plant life, but not all are adapted for practical use and it would be futile to discuss their respective merits. The only remedy used extensively against fungoid parasites is sulphur, and it has been proved to be very efficacious. It is largely used in Kent as a remedy against mould on hops, occasioned by the fungus *Spaerotheca castagnei*, allied to the fungus that causes the vine-disease known commonly as oidium. This fungus was formerly one of the greatest plagues of the hop-cultivators and caused, especially in moist years, heavy losses to the growers; but since the universal application of sulphur this disease has been checked to a great extent.

The sulphur is usually applied before the hops are in "burr" or bloom, with a machine called a sulphurator, drawn by a horse between the rows of plants, an illustration of which appears in No. XXVIII of the *Journal of the Royal Agricultural Society of England*, from which number this description is taken. Two separate applications of sulphur are usually made; the first when the "bine," as the shoots are called, is just over the poles, the second just before the "burr" or bloom appears About 50lbs. per acre is put on at each application, at a cost of about 15*s*. per acre, each time. The sulphurator may be described as a wheelbarrow that when wheeled along turns, by a second smaller wheel attached to the axle, a fan that blows the "flowers of sulphur" with which it is fed, evenly and minutely

between the plant. The sulphur settles and covers as fine powder, stem, branches and leaves of the hop-plant, and covers as well the ground, and destroys by its chemical action the fungoid parasite.

Mr. Morris has ascertained, by the experiments carried on at Wallaha, that when sulphur comes in contact with the filaments and spores of *Hemeleia*, it completely destroys their vitality. This with the experience gained by the Kentish hop-planters, ought to be sufficient inducement to the Coffee Industry of Southern-India and Ceylon to take the matter in hand in right good earnest.

The sulphur must, of course, be applied when the fungus is in its first stage of existence, invisible then to the naked eye. December to March, is given by Mr. Morris as the period during which this stage lasts in Ceylon, and he recommends the mornings and evenings when the dew is on the leaves, as the most judicious time of giving the coffee plant its dose of sulphur; and he states that with an abundant supply of dew, the sulphur blowers completely cover the branches and foliage of the trees with a thin uniform coating of sulphur, which remains on them for several days, even after heavy rain. Soon after the sulphur was applied, Mr. Morris noticed the peculiar pungent smell of sulphurous anhydride or sulphurous acid, generally known as the smell of burning brimstone. There can be no doubt that this sulphurous acid, generated by the action of ozone upon the finely divided sulphur, is the agent which destroys the open and soft structure of the fungoid filaments by its great attraction to oxygen, while it is comparatively harmless to the firm and close structure of the coffee plant. As during this season the coffee plant flowers, it had been feared that the application of sulphur would check or prevent entirely the "setting" of the blossom, but this fear, we are glad to say, was groundless, as the blossom that was on the Wallaha coffee plants, while they were sulphurated, has set most satisfactorily. As the action of *sulphurous* acid during its formation from sulphur and subsequent conversion into *sulphuric* acid, has properly been recognised as the true agent in destroying the fungus, advocates for *direct* application of sulphurous acid are not wanting. "Why," say these gentlemen, "should we waste such quantities of sulphur when its whole action is due to the sulphurous acid which is formed from perhaps only its hundreth part, will it not be much better and more economical to burn the sulphur among the trees, and let the resulting sulphurous acid act direct upon the fungus ?"

We have strong reason to believe that this view is fallacious, the action of sulphurous acid in its *nascent* state, is very different and far more powerful, then when it reaches the fungus, after it has been formed and has combined with the moisture of the atmospheric air. If the *fumes* of sulphurous acid had the same effect, as the *nascent* sulphurous acid resulting from the spontaneous combustion of the sulphur in actual *contact* with the fungus, the hop cultivators of Kent would have adopted the fumigating process long before this.

We are assured that coffee planters cannot do better than follow the sulphurating process, which has been so effectual in checking the former ravages of *Spaerotheca castagnei.*

A letter in the *Ceylon Times*, by a young medical man, Mr. W. G. Wait, warns against the injurious effect of sulphurous acid gas upon plant life. Though, as said above, we do not believe that sulphurous acid *fumes* will be found as efficaceous as sulphur itself, those who are determined to try it, need not be deterred by this false note of warning. Mr. Wait is quite correct in saying that sulphurous acid will seriously injure plant life when inhaled, and the results he gives of placing plants under glass shades, in a confined atmosphere in which sulphurous acid is diffused, are quite in accordance with our knowledge of the action of this gas, but it has escaped Mr. Wait that, under the circumstances he relates, the plant is inhaling the same volume of air over and over again, there being no movement in the air around it, and the want of carbonic acid has probably as much to do with the withering of the plant as the sulphurous acid. Coffee plants in the open, with a continually changing atmosphere around them, will not be affected to the extent, Mr. Wait fears. As a fact, we have seen trees and plants in the immediate vicinity of the sulphur furnaces of a chemical work, flourishing in health and vigour for years; though, night and day, the presence of sulphurous acid gas in the surrounding atmosphere could be detected by its smell.

The use of lime as an alternative or an adjunct means of destroying the fungus is also noticed by Mr. Morris, and, while strongly advocating its use when the diseased leaves have fallen off, and the ground is covered with the orange-spores he deprecates, and we think with some good reason, its use to destroy the fungus in its first stage of existence.

But we would draw prominent attention to what is not generally known, *viz*:—that the presence of caustic lime increases manifold the action of ozone upon sulphur, by its powerful affiuity to the resulting product, sulphuric acid. A small quantity of sulphur mixed with caustic lime will therefore be equally, if not more, efficacious than a much larger quantity of sulphur, used by itself. We would therefore recommend to use in the sulphur blowers, sulphur and caustic lime mixed in equal proportion. The lime should be the best procurable, it should be newly burnt, freshly slaked and finely sifted. A general application of lime by itself, Mr. Morris recommends as a destructive agency in the third stage, when the trees and ground are strewn with the orange-coloured sporangia, and it should be plentifully distributed over the stem and branches of trees, and especially over the withered leaves lying on the ground. The benefit derived from the application of lime will be twofold, its manurial properties being well-known.

That the enormous quantity of bulky, organic manures, that has been used in most estates, has facilitated greatly the development and fruitful propagation of *Hemeleia*, by affording a genial germinating nidus for its spores, is undoubted. We warned, last year, against the exclusive use of oil-cakes, fresh cattle-manure and other similar organic nitrogenous matter in *permanent* plantations, such as coffee and tea, and pointed out what a fertile ground the presence in the soil of a large quantity of organic matter, in a *state of decomposition*, offers to the breeding and development of vegetable and animal parasites. We are glad to see that the *Ceylon Observer* is coming round to our way of thinking.

Mr. Morris' paper is certainly not only the most interesting that has as yet been published on the subject, but it is the most important, as it reveals to us the stage of existence during which we can effectually battle *Coffee Leaf Disease.* The happy result of Mr. Morris' investigations should encourage tea planters to take some action regarding its special enemies—Mosquito-blight and Red Spider.

SOILS—THEIR ORIGIN AND DIFFERENCE.

In travelling through any country which presents diversities of lake and river, mountain and valley, plain and down, any one who has any interest in agriculture, cannot fail to notice the differences which the soils of different districts invariably present. On the margin of some rivers and on the shores of many lakes you have the rich alluvial soil, black with decaying organic matter, which under proper treatment is sure to yield profitable returns. Then there is the hungry, dry, sandy soil that drinks in everything, and seems to retain nothing. Again we have clay, pure and simple, which requires special treatment at the hand of the agriculturist. We have calcareous soils, loamy soils, marly soils, peaty soils, garden soils &c., each requiring a treatment more or less special.

Two questions present themselves :—

(1st.) What is the cause of these differences of soils ?

(2nd.) What is the origin of soils ?

The answer to the first question is implied in the second. If we dig through the soil, we come on what is called the subsoil, this frequently, though not necessarily, has some considerable likeness to the soil proper. It might be desirable to restrict the term soil to that portion of the earthy covering which is stirred by the implements used in agriculture, although, of course, the roots of the crop grown, may reach much deeper. If we accept this definition, then, that which lies immediately beneath the lowest portion disturbed by tillage operations would be subsoil. This subsoil may differ in no respect from the soil proper which lies above it; or it may be clay, tough, friable or plastic ; gravel more or less coarse or fine ; or simply sand. There may be no subsoil even, and if we dig deep, enough, we will at last come to hard rock, rock which may or may not have some resemblance to the subsoil and soil overlying it. No matter what part of the earth's surface we dig through, we come at last on hard stony rock. This rock, or some part of it, is the source of all our soils and subsoils. More correctly speaking, the whole mineral constitutents of soils are derived from the disintegration of the rocks which form the earth's crust. This can be easily shown. If a spade full of soil be washed with water, and the water poured off as long as it continues muddy, the mud kept, and allowed to settle, then burned to get quit of all organic matters, the residue from the washing also burned, then what we have left are a few simple minerals, it may be chiefly quartz, mica, felspar, hornblende, some compounds of lime, alumina, oxides of iron, &c. Now if we take a piece of underlying rock or rather if we analyze the rocks that are found coming to the surface at different parts of the earth, (notably the primitive rocks, from which all others have been formed in the geologic past) we will find, though the number of distinct minerals known to mineralogist is very large, yet the rock-forming minerals are very few—quartz, felspar, mica, compounds of lime, &c., being the most abundant. In fact the very minerals we found in the soil, are here stored up in compact masses all over the Globe It does not necessarily follow however, that the soil is identical in mineral composition with the rock immediately underlying it. This may be so, in some cases ; but in others there may be no or little resemblance in composition. Various agencies may have been at work, glaciers, ice-bergs, ice-floes, change in elevation of surface, rivers, &c., to transport soil-material from distances that at first sight might seem incredible.

The agents, that have broken up, ground down, and scattered the mingled constituents of the rocky crust of the earth, over the world may be classed under three kinds, 1st atmospheric, 2nd aqueous, 3rd organic. It should be borne in mind that each of these agencies exercises a chemical, as well as a mechanical effect.

It is one of the objects of Geology to unfold in detail the various changes that have taken place in the earth's crust in the remote pre-historic past. At present it may be sufficient to say that in Britain, the Continent of Europe and America where these changes have been longer studied, and by a greater number of observers than in any other part of the world, the changes in the elevation of land have been considerable, that a climate of Arctic severity preceded the present, that this again was preceded by a climate and a vegetation almost if not quite tropical. At a still earlier period those lands, then in the course of formation lay under a vast and deep ocean, still earlier it was covered with great forests, interspersed with wide marshy plains over which the great sea again and again asserted its sway. There was a time in the far away past of which Geology alone can tell us anything, when no soil covered the hard rocks, when an encircling restless sea dashed itself to foam and spray against their surface ; and when the electric trump of innumerable volcanoes pealed the prelude to frequent and gigantic upheavals and eruptions. Then came at intervals pauses of rest, broken only by the roar of stormy tumultuous seas, rain dashed in deluges on rock and ocean, and the rush of many waters leaping to their level. No sound of human voice was there, no song of bird nor cry of beast, nor any hum of insect filled the hot sulphurous air, nor did any plant, however humble, lift its head and shed its perfume o'er a world, barren, lifeless, chaotic. As time rolls on, the sweep of tide and currents, and the dashing of the waves have broken in pieces the rocks that fringe the shore. The fragments have been dashed together and splintered, and rolled, and ground down ; and carried whithersoever the swelling waters circulate. The larger fragments lie near the shore, the smaller further out at sea ; and away far out in depths, unfathomable fine particles of mud strew the bottom of a vast central sea to which no ray of light ever penetrates. Pile after pile is added, the mighty weight of water pressing all down, and the internal heat of the earth crystalizing and solidifying, till again in the lapse of ages they assume a solid form ; and it may be are again upheaved to perform the same round.

Then again, far away inland, rain and vapour carried by the atmosphere and deposited on the hard rocks, find their way into innumerable chinks and crannies (produced by the same agents) carrying with them gases of different kinds, oxygen, carbonic acid, &c., and compounds of nitrogen produced by the electric decomposition of the air. These acting on the mineral constituents of the hard rocks formed oxides, carbonates, nitrates and compounds innumerable ; and so eating away the rocks, which are further broken to pieces and disintegrated by every frost, for water in the act of freezing expands in bulk about one-twelfth and thus tears in fragments the hardest minerals, with a force, which nothing material can resist. Rains wash the fragments down to lower levels, rivulets of water, streams, brooks and torrents carry them, still grinding them smaller, and corroding, rounding and crumbling them, till portions are carried down to rivers, and borne on, till where they join the sea and the strength of the river's current is lost, and the particles of matter carried with its tide settle to the bottom, the larger near its mouth to form deltas, the smaller further out to form banks and shoals. Where however a current of the sea sweeps past the mouth of a river, no delta can be formed. The particles are caught up by the stronger sea current and carried to where its force is insufficient to hold them in suspension. Along the banks of rivers they at their mouths, and in lakes and seas into which they flow, we find all the minerals, all the materials organic and mineral which now compose our soils. The power that these agencies have, in changing the whole physical aspect of the world can only be realized by being studied. The examples that occur to us at the moment are the Coast of Spain, the Table Mountain of the Cape of Good Hope, and the Ghauts of India. In these instances whole masses of table land have been carried away, and left hills and ridges to mark the original level of the land.

To determine, when or how organic life first began to play its part on our globe is no part of our purpose at present. It is outside our present object to endeavour to determine what were the beginnings of life, and along what line development proceeded. It is sufficient for our present purpose, that life did appear, and began to exercise its influence amongst the other forces already enumerated, in the formation of soils. We know how a barren coral reef becomes a fertile islet, and if we postulate life, the same causes must have operated in the remote indefinite past of our earth's history. The chemical action of the atmospheric gases, and the operations of rain and sea water, mechanical as well as chemical, break up the rock and cover it with a mineral powder more or less fine, which may be swept into hollows and behind projecting points on the rock's surface. The fine impalpable dust shot out into the air from volcanoes settles down on its moist surface. Fine atoms of organic and inorganic matter revealed only by the electric light are borne on every breeze even to mid ocean ; and washed down by the rain and watery vapour of the atmosphere into the plastic mineral compound, which the other agencies have broken up ready to receive it. Vegetable forms of the lowest kinds are developed on its surface, and decay, thus preparing the way for higher forms of vegetable life. The sea water left by high tides and storms in shallow pools is evaporated by the sun's rays, and leaves its deposits of various kinds, iodides, bromides, chlorides, carbonates, &c., which are again transported by rain and vapour and air, and mingled with the forming soil. Seeds of various kinds are borne by ocean currents to the shores of our islet and cast up on its beach, some of them to strike root, many of them to decay ; and add by the gases and compounds liberated in their decomposition additional material (*See Darwin's Journal of a Naturalist, page 454 et seq*). Here the wandering sea bird rests its weary wing, or it may be makes its home ; and migratory birds of various kinds buffetted by wind

and storm gather strength for further flights, or it may be droop and die, and leave their bodies as a legacy of fresh organic matter to the swiftly growing soil. The great sea throws up its spoil with every wave, molusks that have been crushed in its remorseless jaws. The carcases of creatures that haunt its depths and shallows, are tossed up in its wild woods, and left to swelter and rot and supply the elements of new life.

Year by year the soil deepens and becomes richer, vegetation of a higher kind covers it, this in turn gives way to others, each increasing the accumulated stores of the other ; and so the varied processes of death and life, renewal and decay go on, till trees of statelist kind clothe the surface ; and fruit and flower and insect, and bird and beast, each in their varied order possess it, and clothe our barren rock with life and beauty. Last of all comes man, the Lord of this fair world.

This, very hastily and imperfectly sketched, is an outline of some of the mechanical and chemical agencies and processes which have formed soils. Other agencies, however, have played their part as well in the same great total. Far out at sea, in depths dark and still, to which never reaches the faintest hum of warring wind and water in the fiercest hurricane, creatures, down in the deepest depths, live and move and have their being. Curious and wonderful are they in structure, insignificantly little, but like the coral insect, that builds miles and miles of fringing barrier reef and compasses a continent, these creatures (*Foraminiferæ*) live and die, and in their decay are adding little by little, atom by atom a new deposit to the earth's crust. Creatures of a similar kind in a former age of the world formed all our chalk cliffs and cretaceous deposits. The microscope reveals the identity of the ooze of the Atlantic and the chalk deposits of the tertiary formation.

THE DISTRESS IN THE N.-W. P.

THE effects of a year of drought and famine do not end with the breaking up of the last relief-work, or closing of the last poor-house. In the North-Western Provinces, the residuum of starving pauperism shows no inclination, in these bitter winter nights to leave the shelter of the Government sheds. But even when the last dregs have been drained off, there will still remain, unfortunately, very plain and evident marks of the past time of affliction, to those whose eyes are open, and who have time to think over what they see. One unmistakable and mournful symptom, is the number of suits for arrears of rent. The landlords, as a rule, did not do badly by their tenants while the pressure lasted. There were exceptions, and these too, often of the most inexcusable kind, where wealthy landowners refused, until urged by the district officer, to assist their helpless tenants with food and seed grain. In striking contrast with these were the numerous instances of small resident landlords, themselves too commonly in circumstances of great embarrassment, who manfully stood by their tenantry to the full extent of their means, keeping, the village in comparative safety through the worst days of dearth, On the whole, we are glad to record that the proprietors of land were just and generous to the cultivators during the harvest year from June 1877 to June 1878, which may roughly be taken as comprising the days of sharpest distress. When the year ended and matters began to mend, the landlords set themselves to recover as much as they could of what they had advanced to their tenants. Seed and food they could not sue for in the revenue courts ; but arrears of rent are recoverable by process of law ; and it makes no difference, from a purely legal point of view, whether the harvests of the year have been a failure or a success. The cultivator, in nine cases out of ten, has been unable to pay. He has absolutely nothing to satisfy the arrears due on account of the lost autumn crop of 1877. His spring crop of 1878 was an unusually good one ; and there have been no complaints about the autumn crop lately harvested ; but each of these had to pay its own rent, together with the not inconsiderable addition due for the landlord's advances. Thus there is no means of making good the missing rent ; and the revenue courts have no option but to grant decrees against the cultivators, reserving only, as the extreme limit of mercy, the right to throw the costs of the suit upon the landlord.

Having got his decree, the landlord can execute it by putting his tenant in the civil jail, or by selling him up. Neither process is worth the attendant expense. Imprisonment of a pauper is a profitless amusement ; and the law forbids the sale of the only property which the tenant possesses, namely, his plough and bullocks. In truth, it is for other reasons that these decrees are sought. A decree for arrears of rent is valuable in the landlord's eyes because it breaks the tenant's right to occupancy of his land. In the technical language of the law, it converts him from an occupancy tenant to a tenant-at-will, with this difference only, that he can regain his occupancy rights by paying up his arrears within a certain time from receipt of notice. As payment, however, is out of the question, this privilege is not one of any great account. Occupancy rights, as everybody knows, are acquired by the unbroken possession of a cultivating interest in land, not dependent upon a lease, for a period of not less than twelve years ; and a tenant who has acquired this right, is thereby protected against ejectment, so long as he pays his rent and does nothing to prejudice the owner's right and interests in the soil. Indian landlords are perhaps not much more short-sighted, in the matter of tenant right, than landlords everywhere else. Irish tenants have for years been fighting for 'fixity of tenure,' with very partial success. But it is in India, where the tenant is incomparably more helpless than in Ireland, that the hardship of inelastic land laws is most strikingly seen. It would, indeed, be unfair to blame the laws, or the framers of them, as if they had neglected to protect the weaker side. On the contrary, the Rent Act of 1873 was drafted by a Committee of officers, inferior to no man in the province as regards knowledge of the circumstances of the cultivator, and actuated by the sincerest sympathy with him, and the strongest desire to protect him by all means in their power. Nobody can read the Act without seeing that it makes signal and beneficent provision for maintaining the tenant in all his vested rights. It might be dangerous to go farther, and to tell the landlord that it must depend, in the ultimate resort, upon the discretion of the revenue court, whether he shall or shall not be allowed to enforce the processes granted him by the letter of the law. And yet, if revenue officers had leisure and opportunity to make themselves acquainted with the state of the agricultural population in possession of occupancy rights, such a discretionary power would in all probability be exercised to the real good of both parties. It is sometimes possible to bring the parties to a compromise, by summoning them before the court, and giving them good advice from the judicial chair ; or the subordinate revenue officer may be instructed to do this and report the result. When every expedient has been tried, it still remains too often the case that the landlord insists upon ejecting the tenant, and succeeds in obtaining his desire. But it were useless to blink the fact that in a large proportion, if not, indeed, in the majority of instances, no mitigatory expedients are tried at all, and the order for ejectment is given as a matter of course, upon proof of an unsatisfied decree for rent. This is only one of many examples of the silent and unnoticed operation of our laws in changing the economical condition of the mass of the people. The failure of a single harvest may thus be followed by the wholesale annihilation of rights which have been growing up, under the special protection of the legislature, for half a generation previously : and the chances are that the inconsistency between principle and practice will escape unobserved. The district courts have neither time nor method to notice it ; and the central revenue authorities lose the vital fact in a crowd of annual figures. The fact, nevertheless, remains that one consequence of the past famine has been the loss of the tenant-right enjoyed by a large proportion of the cultivators of the North-Western Provinces.

Occasionally this process presents itself in a lamentably startling shape. A widow, for example, will sue to recover possession of her deceased husband's land. He was a cultivator with occupancy rights, holding a number of fields in common with his two brothers. In the midst of the drought, the whole family emigrate to the Terai, and, finding no means of livelihood there, returned home, where the three men died of want, while the women went back to their parents. Meanwhile the land lay idle till the autumn, when it was given into other hands. The spring crop has been reaped, and the new autumn crop sown, when one of the widows comes forward and claims possession. Of course, to dispossess the actual tenant would be out of the question ; but the hardship lies in the fact that even after his interests have been saved, the widow has no right in the land. Perhaps it would be equitable to acknowledge her right to the land, if she could till it, but no such

arrangement could be enforced under the law. The case is only one out of many. Sometimes it is the occupancy tenant himself who returns from exile, and claims restitution. In every case the result is the same; the landlord contests the claim, and defeats it; and one more specimen of tenant right disappears. The victories to be recorded on the other side are few indeed. The truth is that in contending with his landlord, the cultivator is terribly handicapped by the fact that the village accounts, to which the revenue courts naturally look for the best evidence, are kept by a man who is the landlord's humble servant. Much has been done to improve the system of village account-keeping; and nobody would wish to withhold credit from these efforts, which may reasonably be expected to bear valuable fruit in the future; but it is impossible to deny that the village records at present are a very imperfect safeguard of the rights of the peasantry. A crucial instance of this is sometimes afforded by this very matter of tenant-right. At the time of settlement, some ten to fifteen years ago, large numbers of cultivators were recorded as tenants-at-will; they have continued to hold the same lands ever since, and have consequently acquired tenant-right in them; but the village accountants, whether through negligence or design, have gone on recording them as mere tenants-at-will, to the manifest danger of a failure of justice whenever the nature of their tenure shall happen to be called in question. Again, there are special provisions for relief to the tenant and the landlord in the case of destruction of the crops by sudden calamity, such as hail. Rents are remitted and revenue is remitted in proportion. The remission of revenue is dependent upon the remission of rents; but while the former is a matter that can be effected by a single order of the collector, the latter is one which needs constant vigilance to prevent evasion. If the village accountants did their duty, nothing could be simpler. They have merely to deduct the amount of remission from the recorded rental of every tenant entitled to remission, and to let him and his landlord understand that the remainder alone represents the amount of rent which can be collected. If the rents of the ruined harvest, as not unfrequently happens, have wholly or in part been collected while the State machinery of relief has been elaborating its conclusions,—and delay in these circumstances is always inevitable, and not always to be deprecated—the necessary deduction should be made from the rents of next harvest. One would think that if the village account system were good for anything, it should avail for this purpose. And in fact it is quite adequate, if only care be exercised in supervision. But unless this condition be fulfilled, there is a fair chance that relief will never reach the class for whom specially it was intended, that is the cultivators. With such influences in league against them, the tenantry are ill prepared to meet calamities of any kind.

EDITORIAL NOTES.

ENGLAND imports 130,000 tons of esparto grass and similar paper making materials every year. Many new materials from which paper of excellent quality can be made have lately been brought forward at home, as substitutes for esparto grass; but in most cases their greater cost, as compared with any of the materials in general use, has been an obstacle to their adoption. Recent researches in Scotland have shown the common grass of that country to possess valuable properties for the purpose, and the fact suggests the probability that some of the coarse grasses of India, a nuisance from an agricultural point of view, might be found to contain fibrous qualities suited to the manufacture of good paper. Large areas of land, over which reedy grasses grow with provoking pertinacity to diminish the value of the land for arable purposes, might turn out to be worth cultivating. The *Typha augustifolia*, a large kind of tussock grass, known as *raupo* to the New Zealand natives, who use it for thatching their houses, which grows in enormous quantities in the swampy flats near rivers and lakes, may, like its neighbour, the *Phormium tenax*, prove a worthy rival to the esparto grass of Africa. The *Wiwi*, another kind of grass, coarse, wiry, and apparently useless, growing principally in the interior of North Island, New Zealand, should be experimented with for the same purposes. In New South Wales the "grass-cloth plant" (*Boehmeria nivea*) has already received some attention, being used for the manufacture of a fine kind of matting.

THERE is an anxious article in the *North British Agriculturist*, on the prospects of British agriculture. It calls attention to the generally recognised fact, that farming at home has for long been unprosperous, and that its failure has not depended, as usually believed, upon bad seasons. During the past year the weather in Scotland has been favorable, and bumper harvests have resulted; yet the farmers' position has been in no degree strengthened; and it is concluded that if prices of fat cattle do not increase during the spring months, there is bound to be a heavy deficit this year again on the majority of farms; and there is not at present the remotest prospect of any such improvement.

But attention is justly called to the fact, that the landlords throughout England have shown practical sympathy with their distressed tenants, as the following statement of rent reductions will prove :—

Names.	Amount returned.
Mr. H. Savile, Rufford Abbey	15 per cent.
Earl Manvers	10 „
Duke of Newcastle	10 „
Mr. Foljambe, M.P.	10 „
Mr S. B. Bristowe, M.P.	10 „
Earl Cowper	10 „
Hon. E R. Cust	10 „
Mrs. Colton, South Scarle	10 „
Rev G. C Rolfe, Hailey	10 „
Sir J Noeld, Baronet	10 „
Mr. D Pyke, Somerford Magna, whole of half-year's rent	
Mr. M Biddulph, M.P.	10 „
Mr. Osman Ricardo, Ledbury	10 „
Earl Fortescue	10 „
Sir Hugh Cholmondley, M.P.	10 „
Marquis of Hertford	10 „
Mr. Alsopp, of Hindlif	25 „

In the latter case the reduction took the form of orders to the tenantry for bruised cake or decorticated cotton cake.

THE Paris Exhibition was well illustrated with samples of the many varieties of manure sold throughout France, and we are glad to find that a first-rate display was also made by English firms as recognized by the awards given to British exhibitors. Messrs Ohlendorff and Co. and Messrs. E. Packard and Co. carried off gold medals; Gibbs and Co. and the Nitro-Phosphate Co. silver medals for manures. A London periodical gives an illustration of the Exhibition stand of Messrs Ohlendorff and Co., with samples that for thirty-five years have now been employed throughout Europe, America, and the Colonies with universal satisfaction. The total weight of guano exported from the three Chinchas Islands is stated to amount to 8,000,000 tons. The following countries absorb about 500,000 tons yearly :—England, 140,000; France, 100,000; Belgium, 70,000; Germany, 60,000; various European countries take 50,000. The Eastern United States of America, 35,000; West Indies, 15,000, Mauritius, 20,000. The number of testimonials to the value of dissolved Peruvian guano place it beyond controversy, and manufactories at Hamburgh, Antwerp, Emmerich on the Rhine, Rotterdam, and on the banks of the Thames furnish the world with the greatest of fertilizing agents. In the Paris Exhibition, Messrs. Ohlendorff and Co. exhibited in the English section. Pages of description have been written relative to the several chemical operations to which the imported guano is submitted before it becomes the article of commerce which Voelcker in London, Barral in France, and other well-known experts have tested in their laboratories. Wheat, barley, oats, rye, buckwheat, beet-roots, potatoes, tobacco and rape plants, severally welcome this stimulating and fertilizing manure, which is always guaranteed. Chemistry and agriculture are now in partnership all the world over on the best farms. Taken collectively the exhibition of manures at Paris was a very satisfactory one, and formed a very tasteful series in their ranks of glass cases. Notably in all of them the various elements and processes were displayed with fearless confidence. Farmers no longer believe in *quack* artificials, and the exhibitors did well in calling a spade a spade, and in labelling every article. Messrs. Ohlendorff and Co. exhibited a series of samples of raw guano from the various deposits, including

the old Chinchas; also an interesting collection of the raw materials, being specimens of Spanish pyrites and nitrate of soda used in the manufacture of sulphuric acid, with specimens of nitre cake, pyrites dust, the respective refuse of the raw materials. A collection of twenty medals have been awarded at different agricultural exhibitions to the firm, and to which will now be added the gold medal of the present exhibition. From the circulars in different languages distributed at the stand, the visitor may gather the advantages which Messrs. Ohlendorff and Co., claim for their dissolved guano, and which the special jury consider to merit the highest award in the class. As is well known, the raw guano is variable in quality and faulty in condition, owing to lumps and stones; in the dissolved guano these drawbacks are removed, and the dissolved guano is delivered in a fine, dry, powdery condition, with a guarantee of analysis, so that the farmer is sure of getting exactly what he pays for. About twenty years ago Messrs. Ohlendorff and Co. commenced, at Hamburg, the treatment of raw Peruvian guano with sulphuric acid, and the process proved so satisfactory to the farmer after practical experience, and was so thoroughly in accordance with the teachings of science, that the demand for the dissolved Peruvian guano grew rapidly. We are told that Messrs. Ohlendorff and Co., now supplement their dissolved guano with phosphatic manures, which will doubtless sustain the high reputation of the firm.

Chr. D. Van Lennep, Swedish Consul, at Mahazik, near Smyrna, writes as follows in a late issue of the *Times*:—The cultivation of the willow is recommended by one of your correspondents for districts affected with malaria. His statements on the subject being fully borne out by my own experience in the well-known malaria regions about Ephesus, I beg, through your columns, to call thereto the attention of the authorities in Cyprus. Before the *eucalyptus* was ever heard of in Asia Minor, I had seen the bark of the willow used as a febrifuge. I had remarked the easy and inexpensive reproduction of this tree, its quick growth in damp places, its excellent qualities for fuel and for agricultural implements, and its great advantages for strengthening the banks of capricious streams, and had thence taken every opportunity after the winter floods to stick willow cuttings along the banks of streams and in other damp places in my property; also to scatter plane tree seeds in marshy spots. The result has been that, whereas twenty years ago the full-grown trees in this neighbourhood might have been counted, a luxurious growth of willows and plane trees marks my place, fuel is abundant, fever is steadily decreasing the meandering propensities of my streams are checked, my neighbours have to come to me for agricultural implements, and I have not far to go for timber for all rough purposes.

A disease which appeared in British Honduras some years since, and caused much injury to sugarcanes, has re-appeared there this year, and serious results are anticipated. It appears that the disease first shows itself by a white froth above the roots; that on opening up the roots there is the same froth amidst an abundance of moisture in the roots, and this in dry weather and under a tropical sun. Maggots are bred in this froth, which develop into flies. These flies, when moving about the leaves of the cane, exude moisture from their bodies, leaving stains as they progress; and where such is the case the leaves wither. The loss to crops on a previous occasion when this plague appeared was in some instances in excess of 50 per cent. No remedy or preventive from this scourge is known, or so far as we are aware, has been attempted; and if, from the meagre description given, information can be obtained as to any or what steps can be taken on the appearance of the disease, a great boon will be conferred on the sugar planters of British Honduras.

A Cacao planter in Trinidad states that he has trees which yield him 15, and even in very good years 18 lbs. of clean dry cacao, at a gathering. This is a great, but not an incredible yield, since Purdie got an average of 11 lbs. at one gathering from some old and neglected, but re-trimmed and properly cleaned tree in the garden, and Lunan—1814—relying probably on Blume—1672—says the annual produce in Jamaica's cacao period, two centuries ago, was generally estimated at 20 lbs. a tree, and averaged, good and bad seasons together, 1000 lbs. per acre (equal to 8 lbs. a tree, at 18 feet apart—the usual distance there, at that period), although in poor soil, and under bad management, the yield per tree rarely exceeded 8 lbs. a year. Cacao cultivation in Jamaica died out in consequence of the excessive duty then imposed on it at "home," and the wretchedly small consumption of that day, partly owing to that fiscal imposition; and only now is painfully and with effort struggling to regain a place as a regular cultivation. It is very far from being worthy as yet of coming under the title of a staple of the old Colony.

Most crops are more or less exposed to the depredations of insects at some stage of their growth, and the cultivator has to be constantly on the alert to devise some means to entrap them. In nearly all cases the insects are different—that is to say, different insects prey on different plants—and the same trap is not available. For example, the cotton plant is preyed upon by the army worm, the larva of the night-flying moth (Leucania unipuncta), and the cotton worm, the larva of an olive-brown moth called Aletia argyllacea. From the well-known nocturnal habit of these moths, and the certainty of their being destroyed by a light, a cheap and effective mode of destroying them has been adopted in America. It consists of pans of viscid matter placed upon posts at suitable distances in the cotton fields. A block of wood is placed in the centre of the pan, upon which is seated a lighted glass lantern. The moths, being attracted by the light, dash against the lantern and fall into the pan, and are thus destroyed before depositing their eggs upon the tender leaves of the growing plant. The army worm is arrested in its migrations by ploughing a deep furrow around the field, and making it smooth by drawing a smooth log of wood along the furrow. The worms fall into this, and are unable to ascend the sides. A safe and novel method of killing the worms has recently been invented. It consists of a sheet-iron furnace, having the form of a half cylinder, tapered at the ends, in which a fire is kindled, and this heated furnace being drawn along the furrow destroys the worms. Previous to this invention it was customary to strew dry straw along the furrow and set fire to it, but this was often attended with danger.

The Famine Commission has been making enquiries for itself, we hear, in the Central Provinces, but our officers are so unaccustomed to such enquiries, while the subject itself is surrounded by so many pitfalls in India, that it will not do for them to trust very implicitly to the answers they may receive. The results of certain enquires so made in one district in the Central Provinces, are now before us. The enquires are said to have elicited the following facts, concerning an area of 1,458 acres, occupied by 33 families, consisting of 179 adults and 90 children. The block, for such we presume, it was. seems to have comprised four villages of 277 acres, 441,413, and 324 acres respectively,

Acres		*Cultivated by*		*Adults*		*Children*		*Total.*
277	..	9 families	...	43	...	19	—	62
441	...	9 ,,	...	56	...	29	—	85
413	...	8 ,,	...	56	...	32	—	88
324	...	7 ,,	...	24	...	10	—	34
1,458	...	33	...	179	...	90		269

Thus each family seems to have averaged 8 persons, while the proportion of adults to children is as 6 to 3, very different proportion from what prevails in temperate climates, where children remain children up to 16 or 17 years of age. Again, the average holding of each family is returned at 44 acres—1,458÷33 families = 44 acres—Are we to understand that this is the average size of the holdings, in the district? If we are, the fact shews how radically different is the economic condition of the Central provinces, not only from that of Bengal only, but of nearly all India.

Mr. Juland Danvers, Government director of the Indian railways, observes that it would hardly have been thought possible twenty years ago that a granary for England would have been found in the valleys of the Ganges, Jumna, and Indus. But we have seen during the last four years an increasing production of grain in the provinces watered by those rivers, and a large export trade springing up. In 1871 the export of wheat was 248,522 cwts.; in 1876 it was 5,583,336 cwts., which was sent chiefly to England. Mr. Danvers says:—"When the fibres of Russia were denied to

us during the Crimean war, India stepped in and supplied us with jute, and has continued to do so to an increasing extent ever since. The same may now happen with respect to wheat, barley, &c. A country with a soil and climate capable of producing corn, tea, and tobacco, as well as coffee, opium, sugar, indigo, and cotton, must possess powers which, with the assistance of regular and cheap transport, will be ready to meet any demand that may be made upon it." With Home charges of £16,000,000 sterling a year to meet, and with England the great consumer of the surplus harvests of the world, India is the most legitimate field to which she can look for her supplies.

We quote the *Indian Daily News*:—

"The experiments of the Government in view to agricultural reform sometimes have amusing results. In one experimental farm, the superintendent of which was deeply attached to fowls, a fine stock was obtained, and taken such care of that the birds died of liver-complaint (in medical language *hepatitis*), caused either by excess in eating or in drinking, we are not quite sure which. In another, the superintendent cultivated a quantity of safflower, without knowing anything of the uses to which the flower of the plant is put as a dye. He wanted to try the seed as a food grain. The last brilliant thing, which has come under our notice, is from a farm, called a model farm, in Scinde. From this farm, flourishing accounts have come for some time past of the wonderfully heavy yield of a particular kind of indigenous cotton, to which the farm superintendent seemed to have taken a great fancy. Moved by a spirit of enquiry, and, perhaps, by some other spirit, a manager of another farm got some of the seed of this famous cotton from his brother farmer, and grew it. His report on it is that it is a very prolific, but very inferior variety, —a variety so bad, indeed, that, twelve years ago, the Government spent much time and money in eradicating it from the district of Khandeish, and in preventing agriculturists from growing it. And it is this stuff on which a model farm manager has been spending his time, season after season, for years past. Another of these gentlemen has been experimenting, in order to ascertain whether 'one or a few trees' have any effect in increasing the quantity of rainfall. These things are not jokes; they are written in Government reports, in which one hardly looks for jokes, intended to be such, though one often finds therein things which move to laughter. It has been said that a former Cotton Commissioner once was in doubt whether if seeds were cast into the earth bottom up, the plants would not grow with their branches downwards—standing on their heads, in fact. That story, however, we utterly refuse to believe, and we are convinced it is a base calumny. But, certainly, if one wishes to look for "awful foolishness" of the kind that distinguished the American humourist, when he temporarily edited an agricultural journal, it will be found in the reports of Government agriculturists managing experimental and model farms. Not that they are all alike however: there are managers and managers. One or two of the farm superintendents, employed by the State, do credit to the professional training they received in England, and have proved themselves competent to adapt themselves, and the principles they have learnt to a different climate, and different systems of agricultural practice."

The first object of the new Rent Bill now before the Bengal Council is to provide a summary procedure for the recovery of rents, similar to that by which process on dishonoured Bills of Exchange, is now [illegible]. Whenever a landlord is able to give certain *primâ facie* proof that rent is really due, the Civil Court will compel its payment, under this Bill by summary process.

Leave to defend will be given only on the defendant's paying into Court the sum demanded, or on his satisfying the Court that he has a defence, and on such terms as to security, framing, and recording of issues or otherwise, as to the Court may seem fit. No appeal will lie from the summary decree, unless the ryot deposits its amount with costs, though the Court may, under special circumstances, set aside its own decree and go into the merits of the case.

This provision, or something equivalent to it, is absolutely necessary for the protection of the landlord, in the circumstances of these provinces. We compel the landlord by summary process to pay the revenue, and are bound to provide some summary process to enable him to recover his rent from the ryot, who constantly refuses it from mere contumacy. The judges will be our native moonsiffs, concerning whom Mr. Mackenzie generously testifies that for "purity of motive, ability, and hard work, the moon-"siffs of Bengal will bear comparison with any other similar "body of judges in any other country."

But the Bill has another and more important object, namely to secure something like tenant-right to the occupancy ryot. The dispute has practically reduced itself to the simple question: Shall the ryot be allowed to sell his right of occupancy? And the Bill proposes to answer it by saying, "Yes: but an actual cultivator of the land only." We are disposed to approve of the compromise thoroughly. It is the fruit we may fairly presume, of a suggestion made some years ago by us in the *Indian Economist*, when we wrote—

"It depends upon the State alone, whether we permit the cultivator to clear himself of his liabilities, by selling his partnership in the land to an outsider, who is notoriously unfit to discharge the duties and responsibilities attaching thereto, and who has no claim whatever upon any consideration at our hands. On the contrary he is the legitimate object of our aversion, for the extortion which we know him to have practised upon the cultivator, to his ruin. We will *not* have the usurer as our partner in the land. Neither by custom, nor tradition, nor taste, nor culture, nor by any of the qualities we look for, is he fit to be our partner in the administration of the land. What we want is a *husband* of the land, which the sowcar can never be.

Having ousted the ryot under the cast-iron pressure of our law courts, the sowcar proposes to make him discharge all his duties as of old, while he the sowcar takes the profits. Stated in this shape, we think there will be but one answer to the demand. The sowcar shall *not* be allowed to enter the State firm as partner in the room of the cultivator whom he has ruined by his extortion, and whose partnership rights he claims to have bought. He cannot buy those partnership rights without our consent, and that we refuse to give"

So the ryot is to be allowed to sell his holding, but, says Mr. Mackenzie:—

We hold that it is only the ryot who actually cultivates his own lands with his own hands, or by means of hired labor, who is entitled to occupancy rights. We have no desire to see the money-lender coming in and taking possession of the land, reducing the actual cultivator to the position of a serf. Nor do we wish to see the cultivator following the example of the zemindar, and converting himself into an idler by sub-letting his holding to a rack-rented cottier. We believe that an infinity of mischief is being done by the encouragement given to subletting owing to the construction put by the Civil Courts upon the law as it stands. It is bad enough to have between the zemindar and the cultivator putnidars, durputnidars, seputnidars, howladars, and so on, to the tenth degree, without allowing the original cultivator to begin the process over again on his own account. We propose to recognise no sub-letting and no sub-division of a cultivator's holding without the consent of the zemindar or other rent-receiver. And if the latter consents to subletting by his occupancy ryot, he must accept the latter as a middleman, and the actual cultivator under that middleman will begin to acquire prescriptive occupancy rights.

The Bill evidences an honest freedom from bias, that promises well for its success. All this part of the Bill as to sub-letting, will require careful consideration, and these sections are to be regarded as tentative only.

Last year's report of the Model Farm at Nagpore is not so satisfactory as we could have hoped. The monsoon rain-fall was unusually heavy and it was almost impossible therefore to weed the young crops. The cotton crop it is estimated will not exceed a six anna one, and the jowari a twelve anna one, at the most. But perhaps the most important para. of the report is the last one:—

"There is no doubt that the farm is capable of great improvement. The site was originally selected because it was near Nagpore and near the Ambajhari tank from which water for irrigation, it was thought, would be obtainable. Water is now obtainable, if in smaller quantity than it was at first expected, still in sufficient quantity for small experiments. But the site was not chosen

because of the goodness of the land. On the contrary the soil is for the most part very poor, the fields were far from level, and though much has been done to improve them and the land is very much more valuable than it used to be, still very much remains to be done, and that can only be done gradually as a large grant of money cannot be made available.

We notice from the last report of the Board of Revenue, Madras, that the area of land under indigo cultivation in that Presidency has increased during the past year to the extent of nearly 50 per cent. In the official year 1877-8 the extent of land assessed was 92,000 acres, while in the year 1878-9 the assessment was upon 143,000. The assessment increased proportionately from 2 to 3 lakhs. These facts are worthy of notice in view of the degree to which indigo cultivation is decreasing in Bengal. The growth of cotton, we observed from the same report, considerably diminished. The area in 1877-8 was 560,000 acres and the assessment 6½ lakhs, the figures diminished in 1878-9 to 520,000 and 6 lakhs.

Concerning the wild olive groves in Burmah to which we alluded in our last issue a Rangoon newspaper repeats the question :—"How is it the Forest Department of this province with its large staff of Europen Deputy and Assistant Conservators have not discovered the existence of these valuable trees long ago? Surely with the expensive European training those gentlemen undergo at the public cost on the Continent of Europe as well as in England, we might predict that no valuable trees would long remain unknown in Burma. We remember some years ago that the castor oil tree which grows wild all over Burma was said in some report to produce a very inferior oil as compared with the Indian species. Nothing as far as we have heard has ever been done to improve it, although judging how easily the wild plant grows anywhere, there could not be much difficulty or expense in introducing the castor oil plant which does give a valuable oil. All the castor oil used in Burma is imported just as it was a dozen years ago. The Forest Department might surely endeavour to extend and improve the cultivation of oil seeds of all kinds. Here they would in doing so be interfering with no 'vested interests' whilst helping to extend our export trade and the cultivation of our millions of acres of waste land.'

There is indefinite room we are persuaded for cultivating the forest produce of this vast Empire. American enterprise has discovered a means of getting yet more work out of "the busy bee." Sets of small boxes are placed in the upper part of the hives, which can be drawn out when filled and fresh boxes inserted, so that the poor insects never arrive at the end of their labours. But the great advantage of the plan is that the comb formed in these drawers, being in small compact pieces, can be sold in its original state by the retail dealer; and it is stated that 100 tons of such comb have just been landed in London from America. The bee business appears to be carried on to an enormous extent in the United States. Boats laden with hives are floated up and down the Mississippi, so as to constantly visit fresh pastures of flowers according to the latitude and the season. On land, apiaries are planted at certain intervals in orchards, and other suitable places, for which accommodation a rent is paid by the bee-master. About 35,000,000lbs. of honey are annually made and sold. In strange contrast to this, an English clergyman recently appealed through the papers for a market for his honey. He had actually had to give it away. Is there no honey trade in India?

The list of trees planted during the past year by the Forest Board of South Australia gives one a favorable idea of the exertions that are being made to render Australasia fertile:—

COMMUNICATED AND SELECTED.

AGRICULTURE AND THE PEOPLE IN BUDAON.

Ever since I have been in India, I have given considerable attention to this subject, and have in a small way done my utmost to introduce improvements in the mode of agriculture, staples, seeds, cattle, implements and so forth. So far as my experience goes, it seems hopeless under present conditions to attempt much in the direction of improved modes of agriculture, that is to say in the way of introducing what is termed "high farming." Until capital is directly applied to the cultivation of the land on a large scale, the general level of the agriculture of the country, must remain very much as it is. At the same time, I do not think that the attempt should be abandoned, and I should strongly urge the organisation of a strong well-officered Agricultural Department, whose sole aim would be the general improvement of the agricultural condition of the country. The present Opium Department might at first be utilized for this purpose. As it stands it has a very fairly complete organisation and has dealings with the most industrious classes of the cultivators, and it seems a pity that this organisation should be confined merely to promoting the cultivation of the poppy. With very little trouble its scope might be enlarged so as to include cultivation of all kinds. This Department could extend the present system of giving advances to the cultivators, so as to enable them to produce the more valuable staples on the one hand, and on the other hand, to cultivate the ordinary crops on more liberal principles. Thus the capital which is indispensable to any improvement in the agricultural condition of the country, would be supplied, and a foundation would be laid for further progress.

In the matter of implements very little success has attended my efforts. For the last four years I have carried about with me an English plough and have worked it in the villages almost daily, during the camping season. The people admit the wonderful efficacy of the plough, but the price Rs. 35 to 40, is prohibitive. As a beginning, I should suggest that in each district some twenty or thirty ploughs should be provided by Government, to be let out at small fee to cultivators. I have lent my plough to cultivators on many occasions and they have fully appreciated its value. Again I introduced into Budaon the Beheea sugar mill, but its superiority to the ordinary wooden "kolhu" is so slight, that its adoption does not appear to be probable. In the Terai, however, this mill has proved a great success I believe. Only the other day, however, I introduced a small piece of machinery, of which I have the highest expectations, I refer to Bull's Patent Sand Dredger for sinking wells. The cost of this machine or instrument is Rs. 100, though one of the smaller size can be procured for Rs. 50, I believe. This machine I let out to zemindars and cultivators at a fee of eight annas per diem, and I have had already a sufficient number of applications for it to keep it at work for several months. I have not yet been able to make a detailed experiment regarding the comparative cost of the work done by it and by a native "jham," but I am assured by the manager of the Bilsi indigo factory, who has tried it in a deep well, that the amount of sand excavated is double, while the cost is half what it would be by the ordinary method. If this be correct, the saving of cost in sinking wells by the use of this instrument will be considerable, and ought to be an important factor in connection with the great question of the extension of irrigation by means of masonry wells. I am anxious also to introduce a set of boring tools to be let out at a small fee to persons who wish to sink a well. By preliminary borings, the great risk attending the sinking of a well at haphazard will be avoided, and thus I think a great stimulus will be given to the construction of wells by the zemindars and others. In such small ways a very great deal can be done to help and encourage the people who are marvellously helpless in all matters connected with the introduction of any novelty.

I believe some sort of attempt has been made to introduce improvements in agriculture in the estates under the Court of Wards. Sir John Strachey when Lieut.-Governor, suggested that these estates should be utilized in the way of setting a good example of the results of improved agriculture. I do not think that this suggestion has so far been adopted to any great extent. I should strongly suggest that these estates be

managed and administered by the Agricultural Department. At present the Tehsildar *plus* an unprincipled *sazawal* furnish the management of such estates with results which can be easily imagined by any one conversant with such matters. Were these estates worked properly by the Agricultural Department, they would furnish the very best field for experiments in agriculture. I believe that some such scheme has been proposed by Mr. Buck, Director of Agriculture and Commerce, N.-W. Provinces, and I hope that the suggestion will be favorably entertained.

I am not sure that much can be done in this direction, but I think every effort should be made. The establishment in each district of a seed depôt from which and through which zemindars might obtain improved seed, has been often suggested, and I think the idea is a good one. Such a depôt would involve no cost whatever, as it would be managed by one of the district staff. This officer would indent for the seeds required upon the Director of the Agricultural Department, and thus the Department would be brought into connection with the Districts. At present it has no such connection and its usefulness is in consequence very much curtailed.

Owing to the increase of cultivation, the grazing lands have been much curtailed of late, and in very few districts is there much breeding of cattle. However I think the distribution of good stock will have a good effect in time. There is still some breeding in the Budaon District, and I have indented for 6 bulls to be distributed next season. I have this year distributed 12 half-bred rams which I received from Mr. Buck. The people appreciate them very much, and I hope to be able to report favourably of this experiment. The Stud Department has done wonders for the horses of the country, and I do not see why the same results should not follow from the application of some such system to the improvement of cattle and sheep.

For some six or seven years a very successful Agricultural Show and Exhibition has been held annually at Bulandshahr in the month of March. This Show was instituted by Mr. H. Willock the then collector of the District. To his enterprise and influence the Show is entirely due, and to my mind he deserves the thanks of the Government for having demonstrated by practical experiment how successful and valuable such an exhibition is both in stimulating an interest in agricultural matters, and in bringing the native community together. The Show is not quite so good as in Mr. Willock's time, but owing to the energy of the *tehsildar*, it has been kept up wonderfully well since the departure of Mr. Willock. Till very recently this Show was not officially recognized in any way, and so far owes nothing to the Government, North Provinces. The Show is supported entirely by the contributions of the native gentlemen. The annual income is about Rs. 7,500, which is contributed cheerfully and readily by the native *raises*, who look forward to the *mela* as a Yorkshireman to the Leger. I should like to see such a Show held annually in all Districts, as I am confident that its effect on the native community would have the very best results. I am at this moment trying to organise such a Show in connection with the Kakora Mela in the Budaon District, but owing to the apathy of the authorities, I am afraid I shall have to abandon the project for this year at least.

Land Tenures.

In the Budaon District there are practically only two proprietary tenures, the "zemindari" or undivided, and the "pattidari" or divided. Again the tenures may be divided into simple and complex, or that in which, more or less, one person is the sole owner, and that in which a set of persons holds the estate, either as a united body of co-sharers, or with a more or less complete division of the shares.

As regards the occupancy tenures, the tenant with right of occupancy has in no case any sort of even quasi-proprietary rights, and so far as he is concerned, the question of building a masonry well, does not exist, as no zemindar would consent to such a step, for the building of a masonry well is universally regarded as a mark of proprietary right. The construction of a masonry well for irrigation purposes, is a simple matter in the case of the zemindari tenure, when the owner is a single person or a small set of persons in real union, but when there is a co-parcenary body, with their rights undivided or imperfectly divided or again when the partition though complete is on the "khetbhat" system, as is too often the case, the construction of a well involves many difficulties which will require much discretion and tact to adjust. As pointed out by the President of the Commission, there are almost insuperable difficulties in the way of a compulsory construction of masonry wells. The same difficulties will exist in a modified degree under the alternative or voluntary system, but if the wells are constructed voluntarily it may be naturally expected that the persons benefited will come to some agreement as regards the use, maintenance, &c., of the wells after they have been constructed.

Advances.

As far as I can judge, the only circumstances which stand in the way of the making of wells, &c., is the lack of capital. In another paper I have pointed out that the existing Land Improvement Act is practically inoperative, and that, by a modification of the rules, the capital required might be placed within the reach of the zemindars. My belief is that the zemindars would largely avail themselves of advances for wells and other improvements were advances of capital granted, subject to the payment of moderate interest, which would be calculated so as to repay the capital also within a certain term of years, or better still, as I have suggested in another paper, not repayable, but subject merely to the payment of interest, during the present settlement at a low rate say 6 per cent. Again when the revision of the present settlements takes place the advance of capital would be ignored, and the new assessment would be made in the actual assets. I do not believe for an instant that the payment of interest has the faintest obstructive effect, but I consider that the repayment of the capital, unless it is spread over a very long term of years, has a *prohibitory* effect, and the experience of the Land Improvement Act bears out this view, as no one can be got to take advances under it, because, as I imagine, the capital has to be repaid in large instalments within a stated period. I have made the most earnest and constant enquiries into this subject and I am convinced that with a modification of the *tacavi* rules so as to admit of advances being made at a low rate of interest, but calculated so as to repay the principal after a term of years, or as I prefer, not necessarily repayable, but to be absorbed principal and interest in the settlement, the zemindars will come forward and take advances for the improvement of their estates, and notably for the construction of masonry wells.

The Assessments.

By adopting the latter proposal, the zemindar would be relieved from any apprehension of an enhancement of the revenue in consequence of improvements made by himself. By the system proposed, the zemindar would obtain half of the profit on the capital advanced by the State, without any risk on his part. At present the zemindar has to trust entirely to the tender mercies of the Settlement Officers, regarding whom he is justly diffident. The zemindar is at present not able to assure himself that the Assessing Officer will take into consideration that the improvements in the assets are due to the enterprise of the zemindar, and whatever be the feelings of the zemindar, it is almost impossible for any Settlement Officer, however justly intentioned, to appraise correctly after a term of thirty years how much of the rise in the assets are due to the expenditure of capital by the zemindar, and how much to the unearned increment of the land. It is not to be wondered that the zemindar should be diffident as to the correctness of the view to be taken by the Settlement Officers, Circular Orders of the Board of Revenue notwithstanding.

Remission of Land Revenue.

In the North-West Provinces Rent Act (XVIII of 1873) there is a section under which the suspension or remission of rent and revenue in cases of calamity arising from hail, floods, &c., is authorised. This section is made use of annually in cases of damage by hail storms, but such damage is confined, as a rule, to one or two villages in each District visited by a storm. I believe that the theory on which the assessment is based, is that the profits of the good years should cover the losses of the bad, and judging by the experience of the past season, it is apparently assumed that this margin of profit is sufficient to admit of regular payment even in cases of extreme drought, when the whole of the most valuable harvest has been utterly lost. Thus during the last six or eight months we have witnessed the rigorous exaction of the land revenue in the face of the total loss of the *kharif* crops, while the occurrence of a hailstorm in one or two villages resulted in a local enquiry by a European Officer, in the preparation of elaborate statements and the suspension or remission of the revenue demand in the

imagined proportion of the damage done to the assets of the estate. This is to my mind straining at a gnat and swallowing a camel with a vengeance.

Further, the exaction of the land revenue in Budaon, and I believe in other districts as well, involved a direct breach of faith with the zemindars which has had the very worst effect on the minds of the native community.

At an early stage of the distress the Collector, at the suggestion of the higher authorities, gave the zemindars to understand that unless they came forward to assist their tenants so as to enable them to tide through the distress and to sow the *rabi* crop, the Government would show them no mercy in the collection of the land revenue for the *kharif*. The zemindars as a rule did their utmost to help their tenants, and an enormous area was sown with the *rabi* crop, but to the amazement of the zemindars, they very soon learned that the orders had come to exact the revenue to the full, if possible, and it was exacted ruthlessly. The people are loud in their complaints of the *be'imani* or faithlessness of the Government, and to my mind, with ample reason.

The collection of the revenue in such a season in any case would have been a harsh and impolitic measure, but under the circumstances it must be stigmatized as a *crime*.

The suspension of a portion of the demand for a few months till the *rabi* harvest had been gathered, would have afforded the greatest relief to all classes of the people and would further have encouraged them to believe that the Government sympathized with them in their trials.

On the general question of the system of revenue collection in vogue in these Provinces, I cannot do better than quote one or two passages from a very able and interesting work, lately published, called "Our Land Revenue Policy in Northern India," by Mr. Connell of the Civil Service. He writes as follows :—

"Starting with a tax, which is in many cases considerably in excess of the 50 per cent., and which in some districts constitutes unmistakeably a rack-revenue, there is too much reason to fear that our system is harsh, rigid and grinding to a degree, that we fix a certain sum as the proper amount of the tax, and that we collect it, turning neither to the right nor to the left with a steady, persistent, merciless strictness, worthy only of a Shylock, and not of civilized Government.

"Our system is simply to collect the tax to the last penny through the agency of the *tehsildars*; as the *kists* or instalments fall due, the latter Officer scatters his notices to pay, *dustaks* broadcast over the sub-division. There are now no jungles to fly to for refuge, and there are auction sales which are upheld by the arm of a resistless Government. The Collector knows little and does less. The land-owners feel that mercy is not to be expected, they pay what they can from the rents, and they mortgage or sell their property privately in order to liquidate any balances, for they fear that a smaller sum will be secured if the sale is an auction one, managed by dishonest Government subordinates.

There is in fact no real revenue administration. The Collector, especially in Oudh and the Punjab, is a tax-gatherer and nothing more. He is a compulsory jack-of-all-trades whose days are spent in inditing countless reports on all miscellaneous matters of great and small importance, upon which the local Government of the day sets, or is forced to set, great store. He has to draw up portentous memos on conservancy, municipalities, drains and self-government, all the morning. His afternoons are occupied with his appellate work, and an odd half hour or so, as leisure permits, is with difficulty snatched for the real work of a Collector, namely the disposal of the revenue reports. Those papers which have to do with the future prosperity or ruin of villages, must be perfunctorily rushed through, while the proposal for a new latrine has taken up hours of valuable time. The English correspondence and judicial work must be got through for obvious reasons, but few know or care about the internal state of a district so long as the revenue balance sheet is clear. The register of transfers of landed property may be long enough to stretch from Lahore to Peshawar, but few pay any attention to a trifle of this kind. The revenue has all been realised without much resort to coercive measures, for the mere threat of a *tehsildar* suffices in most cases to drive the land-owner to the money-lender; and the local Government congratulates itself that the largest revenue ever known has been realized in a year of agricultural distress without any noticeable resort to the sterner coercive processes. Those who go among the people, and who really make good use of their cold weather tour, know how grinding is the poverty of the land-owners, who have been forced to borrow at ruinous interest, to mortgage, and to sell, in order to meet the relentless Government demand. So the years roll on, and then perhaps, when half the land in the district has changed hands, the Government wakes up, and the reason is asked in surprise. A culprit is sought, but who can possibly be charged with the crime, for the head of the district has been changed every year, and each officer has governed on the old principle of "after me the deluge."

"It is considered that as a general rule, a good season and a bad season should be held to counterbalance one another. The Government takes no more in a year of abundance than it does in an ordinary year, and therefore the landlord is expected to be able to pay up in full in years of bad harvest. Even supposing this is quite fair as a general principle, in practice it is quite unsuited to the character of the people. They have yet to learn what is meant by prudence and economy, they have no place to keep any surplus receipts, they have rarely, as it is, much to spare, but what they have is at once expended on a long-deferred marriage, in payment of sums due to the money-lender, in buying new clothes or a few trinkets for their families. With men of improvident habits it is absolutely necessary to take what we want from a man at a time when he has the money. It is useless to expect payment at a later period, unless we compel him to resort to the money-lender. Our system, is founded on a direct refusal to consider the habits and character of native land-owners. We fix a demand for thirty years, holding, that what we collect in that period will, on the whole, taking good and bad years together, about represent half of the total receipts. Our system fails, because it will not consider that it is far easier for a native land-owner to pay double in a year of double receipts, and half the required sum in the following year of agricultural distress, than for him to pay the same sum in each of the two years."

In other words, our system of revenue collection is inelastic and does not adjust itself to the circumstances of the people and, further, is not properly supervised by the European officers. The lack of proper supervision has been much aggravated of late years by the frequency with which Officers are transferred from one District to another.

I have already pointed out the blot in the system which excludes two out of three European Officers from all share in the administration of a District and confines them to purely judicial functions. This defect is especially pernicious in its connection with the revenue administration. For several years the local Government, in its annual review of the revenue administration, has urged on district Officers the advisability of utilizing their European subordinates in the supervision of the Revenue administration, but so far, little has been done in this direction.

Prevention of Famine.

Irrigation Works.

It is somewhat surprising that none of the questions under this head has any reference to irrigation by means of wells. However, the memorandum lately published by the President of the Commission shows that the question has not escaped the attention of the Commission.

I think that it should be adopted as a leading axiom in connection with the prevention of famine, that every portion of British India should be provided with the fullest irrigation which circumstances will permit. Canals, tanks and wells are each of them best suited to some portion of the country as a means of providing the necessary irrigation, and I should strongly advocate the organisation of an Imperial Irrigation Department, whose duty it will be to make a survey of the whole country with special regard to its capabilities for irrigation, whether by canals, tanks or wells, or by any combination of them.

I have, in a separate paper, pointed out how the Rohilcund Division of the North-West Provinces is admirably suited to a system of well irrigation, and have expressed my belief that the people will themselves construct wells on a large scale, if capital be advanced on favorable terms. In any case it seems to me the clear duty of Government to take measures to provide the amplest irrigation possible, and the organisation of a special Irrigation Department will best enable this to be done uniformly and satisfactorily.

POSTSCRIPT.

In connection with the questions of the improvement of the agricultural condition of the country, the best means of bringing capital within the reach of the cultivating classes, should, if possible, be discovered, for without the application of capital, no progress is possible. This question attracted the attention of Sir John Strachey when Lieut.-Governor of these Provinces, and he sanctioned a small experiment in the way of an Agricultural Bank, though why this term was applied to the scheme, I do not quite understand. In any case it aimed at giving money advances to the cultivator on the part of Government, very much in the way that the native *soucar* deals with them, with the exception that the rates of interest were much lower.

The experiment was on a very small scale, and so far nothing has apparently come of it. This is to be regretted as it contained germs of the system, which to my mind yields the only hope of any real improvement in the agricultural condition of the country. As illustrating the ease with which such transactions can be conducted under the existing conditions of our administrative system, I would cite what occurred during the past season in Budaon.

In the months of October and November last, the Collector of Budaon advanced Rs. 37,000 for the purchase of seed to tenants on the security of the zemindars, who were invited to come forward and assisted their tenants in this way, if they could not themselves provide the necessary advances. This sum might easily have been raised to Rs. 1,50,000 but for the timidity of the higher authorities who became alarmed at the magnitude of the operations.

Now every pice of this large sum was punctually repaid after the *rabi* harvest in the months of May and June, without the slightest pressure of difficulty of any kind. The money was advanced free of any charge for interest, and I feel certain that but for this help many hundreds of acres would have remained unsown, and many throughly respectable and deserving cultivators would have in consequence been irretrievably ruined. Thanks to the splendid *rabi* harvest, most of the recipients of these advances have been able to pay them back with ease, and are now very little the worse of the calamity which befell them last year.

The moral effect of these advances was also most encouraging. Whenever the District Officers, in the course of their cold weather tour, visited a village which had received advances, they were greeted with the most effusive expressions of gratitude, which were as satisfactory as they were genuine.

I do not see why advances should not be made in this way every year on large scale. The action of Government would at once have the effect of reducing the rate of interest charged by the ordinary money-lenders or *soucars*, and, again, a great benefit would result from the Government being brought into such close and intimate contact with the agricultural masses. The constitution of a strong Agricultural Department, as I have already proposed, would enable this system of giving advances to the cultivators to be carried out in a thoroughly satisfactory manner, and I regard the organisation of such a department as the first step towards agricultural progress.

T. R. WYER.

KHANDESH GOVERNMENT FARM.

(PROGRESS REPORT FOR THE HALF YEAR ENDING DECEMBER 1878.)

At the date of last report (21st July), twenty inches of rain had fallen, or about two-thirds of what is looked upon as an ample monsoon, only the early crops were then sown and those were full of promise which was not however altogether realized, owing to the subsequent months of almost constant rain which ended on the 20th of October, making up the enormous total of 40·89 inches.

2. During the past rainy season the experiment was continued of observing to what extent, if any, the presence of one or a few trees affect the quantity of the rainfall in their neighbourhood. Two gauges were erected as usual, one in a garden well stocked and surrounded by large trees, the position of the gauge being yet sufficiently open for the purpose of ordinary observation, the other was located on the top of a high barn, surmounting the trees, and was thus thoroughly exposed on all sides. The difference in the readings was throughout insignificant, the total for the year being 39·74 inches or about one inch less than on the ground level.

3. The superabundance of rain affected variously and more or less, each and all of the different crops which make up the *kharif* of the district.

4. Of the two kinds of cotton cultivated here, the Hingunghat or "gowram" was uninjured and yielded, both in light and heavy land, a splendid crop. The American variety (Dharwari) suffered from rot in loamy and other rich lands, but gave good returns on light ground. These remarks apply to the district generally as well as to the fields of the farm.

5. In cases where the cultivator's cotton failed, the ground was cleared and resown with bajri, which generally ripened early enough to admit of its being harvested and the field again cropped with *rabi*, of course the abundance of the monsoon alone rendered such practice feasible, thus what was lost on the early crop will be fully made up on the *late*, and the harvest from first to last will be an abundant one.

6. In the case of the jowari, however, the grain will not turn out so well as might be expected from over watering or manuring, this crop becomes excessively luxuriant and developes an enormous weight of straw with comparatively small ears. Much of the farm jowari was ten to twelve feet high, and the crop of 68 acres makes up four square ricks each 49 feet long 22 feet wide and 16 feet high, being nearly double the bulk of any former year's crop, yet the outturn will not be more acre for acre than it was last year. The kurbi (straw) has fallen wonderfully in price, before the rains it was selling at Rs. 8 per cart load, the same quantity may now be bought for 10 annas; with the fall in the price of fodder, that of live stock has as usual gone up, bullocks have advanced from Rs. 60 to 90 per pair, cows from Rs. 15 to 25, and milch buffaloes from Rs. 50 to 90 and Rs. 100 each.

7. The tilly crop although good on the whole, suffered somewhat for want of weeding, the ground hardly once became sufficiently dry to admit of this being done, that the weeds grew up along with the crop and to some extent choked it.

8. The indigo, was similarly hampered, there was also some difficulty experienced in getting the cakes dried and keeping them clear of maggots. Indigo it may be here explained is nowhere extensively grown in this neighbourhood, and always as a dry crop. The mode of preparation as practiced by the Kunbis is very simple, a piece of ground is beaten hard and smooth on the surface and sprinkled with finely sifted wood ashes, on this the pulpy indigo sediment is dropped from the hand in small patches, these take about a week to dry, during which time they are frequently turned over and thus gather up in the process, a large quantity of ashes; this peculiarity although it does not much affect the *local* value of the indigo so produced yet unspeakably debases it as an article for foreign export, and with the view of determining how far the matter might be rectified, an experiment has been in hand for several years; the paste has been dried in frames and cut into squares, according to the most approved system of Bengal and other parts, but the local merchants have not as yet offered a sufficiently enhanced price to make up for the extra labour, and the loss in the weight of ashes, sometimes as much as 10 per cent. of the whole when dried by the ordinary method.

9. A small field was planted with the new Bamieh cotton, which germinated freely, the plants also grew well, some of them attaining a great height, many of them, however, afterwards died off, and altogether the plantation has so far yielded but sparingly. The plant is certainly far from what it was represented to be, and is probably only a sport, if even so much as that from the ordinary Egyptian cotton. As this experiment was lately separately reported upon, it need not be, further noticed here.

10. Statements showing startling returns of indigenous cotton having from time to time appeared in the reports of the Saleru farm in Sind, it was deemed desirable to give it a trial in this Province, and a quantity of seed was accordingly imported when the crop came up, it turned out to be identical with what is known here as *old waradi*, a remarkably prolific but very inferior variety, formerly grown in Khandesh, but wisely eradicated by order of Government in 1867.

11. A small quantity of Nankin cotton seed was also imported from Sind. None was grown on the farm, but a local cultivator made a plantation of it. It has produced a satisfactory crop, but the cotton is in every respect much inferior to the kinds grown here, all the crop has been bought by the farm to prevent its spreading by any chance into the general crop, which is now perhaps the purest stock of the whole Presidency.

12. The sericulture experiment goes on very satisfactorily, three bunds or crops have been matured since the date of last report, the variety was the *deshi* worm of Bengal. It makes a small cocoon of medium silk but is hardy, and better suits the conditions found in Kandesh, than any of the others which have from time to time been tried. The following are particulars of an experiment as to outturn, just brought to a close.

13. On the 1st of November, 400 seed cocoons were selected, on the 8th, moths emerged, and deposited their eggs the same day, on the 17th the worms hatched, and on the 25th of December the bulk of them spun their cocoons, twenty thousand of which were fit for reeling, they are yielding at the rate of 1lb. clean silk to ten thousand cocoons, which will give 2 lbs. of silk as the crop. After the first fortnight one man on Rs. 7 per month was constantly employed in feeding &c., the quantity of mulberry leaves consumed was one gathering of 1-5th of an acre, the

plantation yields four such pickings of leaves annually and requires four waterings, which cost one rupee each per acre. The feeding-house is 36 feet long, 8 feet wide, and 7 feet high, and accommodates 50 feeding trays in five tiers on a wooden frame, the runs of the trays are broad, with bottoms of bamboo matting, they measure 3 feet 4 by 2 feet 4, and two inches deep, each holds 1,000 worms of the small monthly kinds or 600 of the large annual stock. The house is built with walls and roof of clay and cost Rs. 25. Several local gardeners have lately planted mulberries, and bring the leaves to the farm for sale, altogether the present prospects of the experiment are very encouraging. When mulberry shall have become more abundant in the neighbourhood it may be desirable to introduce improved reeling machinery, as upon this process the value of the silk mainly depends.

14. The teosmté seed sown on the farm produced a very heavy crop both in grain and fodder, it grows freely and all kinds of live stock are fond of it, both in the green and dry state. It bears transplantation and separation of the roots and is likely to prove a useful plant where a necessity exists for growing green forage, a one acre plantation is being laid out and the result will be given in figures in next report.

15. The seeds of the rain tree sent to the farm about 6 months ago turned out well, the tree is of easy and rapid growth, many have already attained a height of one to two feet, and all are healthy. The tree seems in every way suited to roadside planting.

16. The windmill pump has been re-erected and worked since the rains, and continues to give satisfaction, although the necessity for building a tank will always be against it as an *agricultural* machine.

17. Four new ploughs have lately been received and tried after having failed at Ahmedabad. Two of them are small *Turnwrests*, one each of wood and iron, these are constructed for ploughing hill sides; so that their capabilities can scarcely be tested on low land. One is a single moulding plough by the Boston Plough Company, and would be a useful implement in soil to which it is suited, a second by the same maker is a peculiar kind of double moulder, and works pretty well in garden land.

18. As much uncertainty exists concerning the quantity of water actually required by any irrigated crop, a series of experiments has lately been commenced with the view of determining the same. A fall board has been erected and a careful register is being kept of the water which passes over it. There can be little doubt that the very best land may readily be destroyed by over irrigation and *that* is particularly likely to take place where river water can be run on to the ground with little trouble, proofs of this are unfortunately only too abundant in the Punjab, Sind and other parts where inundation-irrigation is extensively practised. The Government farm at Salaru too is becoming sterilized by kálár. One field on the farm here is the subject of experiment to determine the rate at which this process goes on. After three years watering from the Jamda canal, a faint efflorescence appeared on the surface last season for the first time. This year it is more abundant and wheat has refused to grow in parts. I mean to continue irrigated crops yearly and note the result.

19. The strength of the herd has been increased by one Hereford bull, while two Amruth mahal bulls have been sent out in the district. The total home strength of the herd is at present 168, and made up as follows :—

Bulls of different breeds	...	25
Cows ditto	...	63
Steers ditto	...	21
Heifers ditto	...	46
Calves ditto	...	13
		168

20. Animals suffered a good deal at the commencement of the cold weather, from a disorder known as "khurgutti," the parts affected are the mouth and the feet, and is on that account often mistaken for foot and mouth ill proper, although really nothing more than a severe form of the fouls, or foul-of-foot of European countries. As many enquiries on the subject have lately been made, I may here state the treatment we have found most satisfactory in every respect. When the tongue has become sore and the animal refuses food, the upper surface is rubbed briskly twice a day with a mixture of pounded turmeric and common salt. The feet are kept clean by frequent washings with salt and water. If maggots make their appearance they are easily dislodged by means of tweezers after diluted carbolic acid or turpentine has been dropped into the sores. If promptly treated, recovery is rapid, but when the disease is allowed to get into its advanced stages the tongue rots and the hoofs sometimes fall off, and the animal is thrown out of condition for months.

21. The distribution of the farm cropping this year is as follows :—

Ordinary grazing ground	...	623 acres.
Meadow	...	54 „
Kharif (early crops	...	357 „
Rabi (late crop)		
A.—Irrigated 73 acres.		
B.—Dry 41 „	...	114 „
Gardens	...	10 „
Experimental Plantations	...	5 „
		1,163 „

Full details of the results of these crops will be available by the date of next report.

A. STORMONT,
Superintendent Government Farm.

BAMEIH COTTON.

FROM
THE SUPERINTENDENT GOVERNMENT FARM,
TO
The Collector of Khandesh.

SIR,—I have the honor to report the results, so far, of the experimental sowing of Bamieh cotton made here under Government Resolution No. 1257 of 9th March last.

2. The quantity of seed received was one quarter of a pound. A few packets of 100 seeds each were given to cultivators for trial, the remainder was sufficient to sow about 3 quarters of an acre.

3. The ground selected had been previously prepared for sugar canes and was rich in manure, and in excellent tilth. The seeds were planted on 28th June in lines four feet apart and four feet also from plant to plant, about 75 per cent. of the whole germinated, and the plants made astonishing progress for a few weeks when they were attacked by *aphis* which considerably checked them. After a time these disappeared and the plants started afresh and rapidly shot up to heights varying from 6 to 10 feet.

4. A very promising show of flowers was succeeded by a somewhat scanty supply of pods, a large portion of the former having been beaten to the ground by the heavy and persistent rains which also capped numbers of the plants.

5. The surviving trees have yielded only a few pods each, bringing up the entire crop, so far, to about 3lbs. of very long, but somewhat weak seed cotton. The trees are again sprouting luxuriantly from the roots, so that a second crop may be got further on in the season.

6. Although it is very improbable that the Bamieh cotton will be found suitable to a soil and in a climate such as that of Khandesh, yet the completeness of the failure in this case is certainly to some considerable extent owing to the unusually heavy rains, which in—Black land damaged severely even the hardy Dharwar American variety.

7. With regard to the history of the Bamieh cotton, I venture to think that some element of error must have crept in, in making the observations on which it has been framed. There is really little apparent difference between it and the ordinary Egyptian cotton, with the exception perhaps that the habit of the former is less bushy. The flowers, the seed, and the cotton of the two are scarcely to be distinguished.

8. Full particulars of this experiment will be available by the end of the official year.

A. STORMONT,
Superintendent.

Bhadgaon, 14th December, 1878.

AMERICAN HONEY.

AN experiment which has been successfully carried out by a firm of American wholesale grocers, is note-worthy as the first step to the introduction, probably on a large scale, of American honey in the comb. Last year a considerable trade was done in the exportation of honey from the United States to Europe, one New York firm alone sending over 300,000lbs. of honey, principally to Great Britain. The bulk of this, however, was sent in jars, either as pure extracted honey or as comb-honey—that is, honey bottled with portions of broken comb remaining in it. In the United States, however, honey, when sold in the comb, commands a much higher price than the honey sold in jars, and the efforts of honey-dealers there have long been directed to the production of small, clean, compact and perfect sections of honey-comb in a form readily saleable by the retail grocer. This object has been effected by placing sets of small boxes in the upper part of the hives for the bees to store the surplus honey in, and as each box is filled it can be lifted out and replaced by an empty one in which the bees may continue their labours. These boxes are now commonly made with four glass sides and a strip of wood at top and bottom. In size they are a square on five inches on the side by two inches in thickness, and a dozen of them are packed together in a crate for shipment. The advantage of using this particular form of box is that the bees finish off the section of comb in the shape and quantity found to be best adapted for sale and the seal of the bees upon each cell is the best guarantee for the purity of the contents. The difficulty of exporting these delicate pieces of comb without the loss of a great part of the shipment by breakages has hitherto prevented the growth of what might doubtless be a lucrative business. During four years Messrs. H. K. and F. B. Thurber and Co., of New York, have tried to get this comb-honey to England

in good condition, but without success. The want of proper machinery for unloading the ships seems to have been the principal cause of the damage. "Let down with a run" by a sling from the yard-arm, the glass boxes and their fragile waxen contents were again and again broken and spoilt. In November last, however, Mr. W. M. Hoge, the manager of this firm, succeeded in landing a consignment of 80 tons in Liverpool, and, encouraged by the result of the venture, he landed, at the London Wharf in Wapping, a lot of about 100 tons brought over in the *California*, one of the Anchor Line of steam ships. There are 2,500 cases in this shipment containing over 200,000lbs. of honey, and few boxes have sustained any injury in transit. Taught by past experience, Mr. Hoge had his cases securely boarded up between bulk-heads on the steamer, and in unloading employed gangs of men to pass the cases hand over hand down the ship's side into the lighter and from the lighter on to the wharf. Visitors to the Paris Exposition, where Messrs. Thurber and Co. obtained a medal for their honey, as well as one from the French Agricultural Society for the best honey in the most marketable form, may remember the exceedingly neat appearance of the honey-comb in these patent hive boxes.

The importance which bee-keeping has assumed as a regular branch of industry in the United States may be conceived when it is stated that over 35,000,000lbs. of honey are produced and sold annually. The tendency in this as in other occupations has been for the trade to be carried on by persons having large capital. The bee-keepers have frequently from 2,300 to 5,000 swarms of bees, and some far larger numbers. Messrs. Thurber and Co., for instance, have about 12,000 swarms of bees. Of course it is only by a thorough organisation that such large numbers of these little workers who toil without pay can be looked after and cared for. The system in the United States is to farm out the swarms. Arrangements are made with farmers and those who own orchards in suitable localities to allow an apiary of perhaps a hundred swarms to be placed in their grounds. At a distance of three or four miles another apiary will be placed with some other farmer. For this accommodation either a fixed rent or a share of the honey produced is paid, and the bee-owner sends expert workmen to clean the hives, to take out the boxes of surplus honey as they are filled, and to destroy the moths, grubs, and other creatures that take advantage of the bees' frugality. As showing the lucrative character of this business, it is said that a firm of shippers paid to one bee-keeper for his season's crop of honey a sum larger than the salary of the President of the United States. It is estimated that on an average one acre will support 25 swarms of bees, and, as the yield of a swarm is generally about 50lbs. of honey, it is evident that this trade may yet be greatly developed. Already the firm above mentioned, in addition to a corps of experienced bee-men to tend the hives, find occupation for nine men and two steam saws during five weeks of the year in cutting up the timber for the 72,000 boxes used to hold the comb-honey. The glass-makers also find some custom from the honey dealers, 144,000 panes of glass being required to make the sides and ends of those boxes. Much attention has been paid in the United States to the improvement of the breed of bees, and queen bees have been imported from Italy, Cyprus, and elsewhere for the purpose of improving the stock. Some years ago fine Italian queen bees were sold for as much as £10 each in New York, but by forming nurseries and rearing queens carefully selected from fine broods, queens of good blood, if a term may be borrowed from the turf, may now be bought at prices ranging from $1 to $5 each. Side by side with improvements in the culture of the bee, too, there have been many ingenious contrivances introduced in order to save the time and labour of the bees and of the honey-dealers. About ten years ago a German suggested that thin corrugated sheets of wax, which he called " artificial tablets," should be provided for the bees to make their comb from. These, however, did not come into general use, but a few years ago Mr. W. H. Hoge, effected an improvement by starting the side walls of the cells. When these " foundations," as they are called, were presented to the bees, the intelligent little creatures at once took advantage of them and extended the side walls so as to form the regular hexagonal cell. The machine by which the impression is made on both sides of the wax is very simple, and somewhat resembles a clothes wringing machine, only the iron rollers are studded with little hexagonal-headed pins just the size of the section of a cell, so that, when the thin sheet of wax is passed through, the wax is pressed up between the pegs to the height of about 1-16th of an inch, thus indicating the position and offering the substance for the construction of the cell walls. Another remarkable adaptation of machinery is afforded by the use of a rotating frame, which causes the cells of the con[illegible] placed in it to be emptied by centrifugal force. The empty, uninjured comb is afterwards replaced in the hive and again used by the bees. As about three-fourths of the time of the bees, it has been computed, is taken up in the construction of the comb, it will be seen that by these contrivances a great saving of bee labour is effected. With the rapidly increasing supply obtained by this well-organized system of bee-keeping, the dealers in honey in the United States are already trying to open new channels for the trade and to create fresh uses for the product of the hives. With this object in view a prize has been offered by the American Bee-keepers' Association for the discovery of a method of converting honey into the form of a crystalline sugar. Looking forward to a time, not, probably, far distant, when honey will be produced as cheaply as raw sugar,—honey may now be bought wholesale for 7 cents per lb. in California—the dealers hope to be able to provide a substitute for glucose which will equally well serve the purpose of the cook, the confectioner, and the brewer.

THE AGRICULTURAL CONDITION OF MYSORE.

We drew attention to an article in one of the leading English Agricultural papers on the condition of our agriculture as guaged by comparative statistics. We now furnish similar ones for Mysore, as shown in the Administration Report on 1874-75, a report written before the influence of the famine was felt. The total area cultivated in any way, whether as wet, dry, garden, or coffee, may be classed as follows :—

Cereals furnishing food	87·8 of total cultivated area.
Industrial crops	5·4
Garden crops (including coffee)	3·6
Perennial crops	3·2

We note, too, that in ten years the area cultivated with superior grains, forming the food of the bulk of the population, increased from acres 2,198,476 to acres 4,054,181, showing either the land diminished in productiveness, or that the demand was intensified year by year by increased population and export, or that both causes were acting together. It is difficult to classify these crops as exhaustive or restorative in the way crops are so considered in England, unless, indeed, we consider all but garden crops exhaustive. We can, however, arrive at a useful comparison by comparing the quantity of live stock in Mysore, which, as far as can be ascertained, is practically stationary in numbers, with that of England. In 1875 Mysore possessed

		Per square mile of territory. Mysore.	England.
Cows & bullocks	29,21,962	108	66·5
Sheep & goats	21,84,594	86	825·0

On to bring it to figures that will give an idea of the manure supply per 100 acres of arable land by calculating five sheep equal to a bullock, and including other stock in proportion, we get in Mysore

	Per 100 acres arable land.
Cows and bullocks Sheep and goats, calculated to cattle Other stock ditto ditto	104 head.

or about a bullock per acre for cultivating and manuring.

We presume the agricultural authority in Mysore has brought these facts to the notice of the Famine Commissioners, who will, we fear, glean a very imperfect notion of that province by their visit to Bangalore Even if they have time to visit its environs they will see anything but an average tract of country. The paddy-lands and ragi-fields surrounding the town are heavily manured, the market gardens are the finest in the province, and numbers of fine cattle used by the cartmen are far above those usually employed by the ryot. Ocular evidence is so impressive and so much more likely to be lasting than knowledge acquired by reading papers that the real condition of Mysore is hardly likely to be believed unless a journey were taken, not through a selected tract of country, but across fifty miles as the crow flies. Mr. Elliott knows much of the province, as also does Mr. Runga Charlu, but how can Mr. Caird glean the exhaustive facts about its agriculture and agriculturists that he pre-eminently should possess before giving a verdict? We fear the cry " Perish India" raised by the opposition to the party in power in Parliament, would receive too many facts to favour it, if our agricultural distress be brought too prominently forward; hence we have actually heard it reasoned, the evident straining to show selected areas that but too favourably represent the average condition of the country.

EXPERIMENTAL FARMS.

Resolution by the Government of India.

In his despatch dated the 7th February 1878, the Secretary of State noticed an experiment at the Nagpur Model Farm in 1876-77, where, in consequence of irrigation and manuring, Jelalia wheat produced 1,600 lbs., and white-eared wheat 2,200 lbs., an acre, the average yield per acre in the country being only about 400 lbs. The value of the produce at Nagpur was estimated at Rs. 60, while the cost of cultivation, including all expenses, was given at Rs. 10 per acre. His Lordship desired to be informed " what steps are taken in the above and other provinces to impart to the agricultural community generally the lessons to be learnt from the operations of the model and experimental farms ;" and observed, " as in many cases these farms appear to involve financial loss, it is the more important that their results, when satisfactory, should be utilized to the utmost for the general good of the country."

2. A copy of this despatch was circulated on the 21st March 1878 to the Governments of Madras, Bombay, and the North-Western Provinces and Oudh, and to the Chief Commissioners of the Central Provinces, British Burma, and Mysore, with a request for a report in connection with the farms maintained under their orders.

3. In Mysore, the Chief Commissioner states that no general steps have hitherto been taken in the direction indicated, the condition of the province during the past two or three years having forbidden any such measures. Mr. Harman, the superintendent of the Bangalore Farm, has recently been authorised to make tours in the province twice in the year, once in the summer when the *ragi* crops are being sown, and again during the winter months when the crops are being reaped, in view to his acquiring practical experience in the native systems of agriculture and imparting to the ryots by personal communication and by experiments the benefits of deep ploughing, as also the advantages to be gained by the use of improved seed. The Chief Commissioner has also under consideration a scheme for placing one or two plots of land in each district under the charge of a village patel or other suitable person, who would cultivate the land in accordance with instructions from Mr. Harman. "By this means," the Chief Commissioner observes, "it is hoped that the ryots will have an opportunity, which the location of the Government Farm at Bangalore does not afford them, of judging of the results to be obtained by a better system of farming." Since these remarks were written, however, it has been decided to abolish the Bangalore Farm and to transfer the services of Mr. Harman to the Bombay Presidency.

4. In Burma, the only Government Farm is one established at Myouktoung in the Aracan Hill Tracts for the purpose of growing and curing tobacco. As regards the cultivation of tobacco on the low lands lying along the banks of rivers, the natives have but little to learn: the farm was started with a view of testing the capabilities of soil in upland tracts, and more especially for the purpose of teaching the people an improved method of curing the leaf; but there has not been time to judge of the results as yet.

5. Mr. Buck, Director of Agriculture and Commerce, North-Western Provinces and Oudh, in reporting on the subject, refers to that portion of the minute recorded by Sir John Strachey in November 1874, proposing the formation of a Department of Agriculture in the North-Western Provinces, in which it was suggested that a good means of reaching the agricultural community would be by experiments in the estates under the Court of Wards. This suggestion, it is said, has been carried into effect, though not to so great an extent as was desired, in consequence of the drought of 1877. To some estates, however, improved English ploughs, improved sugar-mills, and selected seeds, were sent; and in some districts, where the local officers took an interest in agricultural matters, seed and implements were distributed to estates other than those administered by the Court of Wards. As a further means of introducing improvements to the notice of the agriculturists, Mr. Buck lays great stress on the advantages of agricultural fairs; and he proposes to give greater encouragement to such fairs in future years. No attempts seem to be made by the Local Government to bring directly to the notice of the natives the results of the experiments conducted on the State Farms.

6. There are two Government Farms in the Bombay Presidency, one at Bhadgaon in Khandesh and the other at Salaru in Sind. At Salaru, nothing has as yet been done in the desired direction; but the superintendent proposed making a tour in the cold weather months, during which he would acquire and diffuse useful information. He is to report the results of his first tour, in order that the Government of Bombay may be in a position to judge of the desirability of repeating the experiment.

At Bhadgaon, too, little appears to have been attempted. The superintendent reports that the instruction is imparted through farm apprentices, farm servants, and visitors. The system of apprentices, if carefully worked, would no doubt prove useful; but nothing can be expected from farm servants as a means of imparting agricultural information to the native community. Mr. Stormont, the superintendent, recently visited Madras and Bangalore, under authority from the Government of Bombay, with a view to ascertain the system followed on the farms at those places; and he was instructed to report the result of his enquiries on his return to Khandesh.

The Local Government has also, after consultation with Mr. Robertson of the Sydapet Farm, decided on commencing a system of agricultural education in the Deccan, and probably, in due course, the Bhadgaon Farm will be made subsidiary to the scheme of instruction.

7. In the Central Provinces, Major Macdougall, the superintendent of the Nagpur Farm, proposes to publish the results of "any decidedly successful experiment" in the *Rural Gazette*, a paper printed in Hindi, Mahrathi, and Urdu by the Educational Department, of which a copy is sent to every Government school in the Central Provinces. The Chief Commissioner approves of this proposal; but such a means of making known the operations of the farm seems scarcely to be what is required, the record of these experiments being useful to the agricultural community only when they can be followed and explained on the farm on which they have been tried.

8. In the Madras Presidency, good and useful work is being done under the supervision and guidance of Mr. Robertson, the superintendent of Government Farms. Attached to the Sydapet Farm, on which experiments of various kinds are tried, is an Agricultural College, in which a complete course of agricultural instruction is afforded, and which is intended eventually to accommodate upwards of one hundred students. In view to a further diffusion of information, Mr. Robertson has proposed the establishment of small agricultural experimental stations all over the Presidency, each being placed in charge of a trained agriculturist, who is also to conduct an elementary agricultural class. This scheme is, however, at present in abeyance for want of funds.

Recently, a very interesting ploughing competition was held at the Sydapet Farm, in which European, American and native ploughs were used, the competitors as well as the visitors from different parts of the country being very numerous. Such open competitions as these afford an efficient means of interesting neighbouring cultivators in the methods and processes of the improved system of agriculture practised on the farm. The public reports shew that the exhibition was watched with very great interest and was completely successful.

9. From the facts summarised above, it may be said generally that only in the North-Western Provinces and Madras is any real effort being made to teach agricultural reform to the people. In the North-Western Provinces, a Department of Agriculture and Commerce has been created, with a Director at its head, whose special duty it is to organise the collection of agricultural and commercial statistics; to direct experiments for agricultural improvement in model farms and elsewhere; to watch and report on the progress of trade, and to suggest in what directions it may be developed, or hindrances to its prosperity removed; and to investigate facts connected with the condition of the agricultural classes. The scope and objects of the Department are clearly explained in a minute recorded by Sir John Strachey in November 1874, to which the attention of the Local Governments and Administrations was drawn in the letter from this Department dated the 11th August 1875, Nos. 11—426-433, regarding the collection of agricultural statistics.

In Madras there is a Department, which, though not as yet formally recognised as a Department of Agriculture, is practically one, with an efficient and well qualified director at its head; but its expansion has hitherto been greatly impeded by various causes, not the least among which has been the want of funds.

10. In other provinces very little is being done, nor as matters stand can much be expected. Experimental farms indeed, when they stand alone, are of comparatively small utility. To be really useful they should be part of a system of agricultural instruction; they should be attached to a school where sound agricultural instruction is conveyed in class, and they should be the field for carrying into practice in the presence of students the theories of which the lessons have been explained to them in the class-room. If the students are taken from the classes dependent on the land for their living, satisfactory progress in the diffusion of agricultural instruction under such a system will soon be apparent. It is with much satisfaction that the Government of India has watched the recognition of these principles in Madras and the efforts that are being made there gradually to mature a complete system for their application in practice. The system for action in the same direction which has just been proposed by his Excellency the Governor of Bombay is also gratifying as indicating the interest taken in the matter by the Government of that Presidency. In other provinces much cannot be expected under the present system, though, defective as it is, the farms, if they are carefully and intelligently managed, intelligently supervised, and placed on a substantial and permanent basis, must gradually do good, and the Government of India desire again to commend the subject very earnestly to the attention of Local Governments and Administrations. Bengal especially is a province which is singularly deficient in opportunities for agricultural instruction, while it is perhaps of all Indian provinces the one where a reform of practice is most needed. It is also the province of whose agricultural resources and capacities the governing body knows least. It is a matter of more than ordinary importance that the cultivating and wealthy land-owning community in this great province should be taught to realise the advantages of a better agricultural practice, and that steps should be taken to remove the reproach which now exists, that the very elements of agricultural information, such as the average yield of particular crops in particular soils, are wholly absent. Efforts in this direction were made some years ago by Sir George Campbell; but these efforts, though well intentioned, were frustrated by radical errors in the selection of sites for farms, as well as in the selection of superintendents. The results were so unsatisfactory that the farms were broken up one after the other, the last being abolished in 1877, on the ground that all the attempts which had been made to teach agriculture to the people of the country had ended in failure. This conclusion was not accepted by the Government of India, and it is desirable in connection with the present question that the views then expressed to the Government of Bengal should be brought prominently before other Local Governments and Administrations. In the letter from the Government of India to the Government of Bengal dated the 4th May 1877, No. 91, it was said:—

"His Excellency in Council is by no means prepared to admit that, because it is not necessary at present to teach to the natives on a scientific basis all the technicalities of the highest farming, there is therefore no opening for instruction of a highly useful, if of a more modest kind, adapted to the present educational and agricultural standard of the country. His Excellency in Council is unable to agree with his Honor the Lieutenant-Governor in the opinion that the attempts of the Government to teach agriculture to the people have failed everywhere. Where these attempts have failed, as at Poosah, failure has been the result of inefficient management; but where ordinary care and attention have been intelligently given to the subject, it is unquestionable that, as at Sydapet in the Madras Presidency for instance, good results have ensued.

"5. It is not necessary to employ specially qualified agricultural chemists for the purposes contemplated by Government in the establishment of model or experimental farms. The objects of the Government have been frequently stated, but they have been well and briefly summarised by Sir John Strachey in the following extract from his minute of the 28th November 1874, proposing the creation of a Department of Agriculture and Commerce in the North-Western Provinces:—

"'The object of these model farms should be three-fold: first, to obtain complete information, based on actual facts, as to the average productiveness of different crops on the different classes of soil on which they are ordinarily cultivated, and the cost of cultivation; secondly, to establish and prove to the agriculturist the advantages to be gained from small improvements, such as they are able themselves to carry out under existing conditions, such as deeper ploughing, economical use of canal water, selection of seed, &c., thirdly, to make experiments as to staples and industries which it may be possible to introduce if new, or to familiarise and improve if already existing in the country. The extension of sericulture, the improvement of indigenous fibres, and the manufacture of a finer class of tobacco, may be mentioned among the objects of such experiments."

"It is to these objects that attention should be particularly directed. It is evident that lessons in such matters, especially under the second head, and instructions in such details (important though they are) as the proper storage and application of the manures ordinarily employed in the country, shewing experimentally how they may be made to retain all their fertilising elements, of which much is now wasted, the proper treatment and breeding of live stock, improvement of the implements employed, and other similar matters, may as successfully be imparted by an energetic man of fair intelligence, possessing an adequate practical knowledge of modern farming, (and consequently having such knowledge of agricultural chemistry as is essential to the successful pursuit of modern farming), as by a professional chemist of high scientific attainments.

"The Governor General in Council is convinced that lessons of this kind are urgently needed, and that if measures for the elementary instruction in such matters of the agricultural community are persevered in by the Local Governments (without whose cordial co-operation nothing can be done), they cannot fail after a reasonable time to have very considerable effect upon the cultivators in the neighbourhood of the Government farm and through them upon others further away."

11. The excellent results which have followed the creation of a Department of Agriculture, and Commerce, in the North-Western Provinces, in the impulse which has been given by it to agricultural enquiry and improvements, indicate perhaps the best form in which Government action can be directed to the promotion of the objects in view. With the establishment of such a Department in each province (and it is maintained in the North-Western Provinces entirely from provincial funds) the extension of the system, whether by agricultural instruction in schools, or by practical teaching in experimental farms, or where means are available by a combination of both, could be regulated under efficient control and advice according to the particular requirements or circumstances of each province. From this point of view the Governor General in Council will be glad to learn that the matter has again received from the Government of Bengal and other Local Governments and Administrations the consideration which its importance merits, and he would wish to be informed at an early date of the results of that consideration.

PROFESSOR WILSON ON FRENCH AGRICULTURE.

THE Class of Agriculture in Edinburgh University was opened on November 18, by Professor Wilson, who directed attention in his introductory address to French agriculture. It was, he said, of great benefit to agriculturists that they should become acquainted with farming as it was carried on throughout the Continent, seeing that one could not pass through any well-farmed bit of country without noting new practices, which, if carefully studied, might be found suitable for application at home. In the summer he had, he mentioned, visited Paris in company with Mr. Fletcher Menzies, to attend the International Agricultural Congress, and when there he had an opportunity of examining the different kinds of French stock. Of cattle there were some fifteen distinct breeds, kept principally for working purposes. In the front rank of these stood the Charolais, which were admired by everybody, and which in their points, appearance, and quality were equal to some English shorthorns. In several of the breeds a marked improvement had been effected by crossing with English sires—a fact which showed that it was better to seek after the improvement of a native breed than merely to set about supplanting it altogether. Among their sheep, which it was well known were for the most part merinoes, crossing had also been introduced, with what success might be judged when he mentioned that two pens were shown to him, the one containing high-class pure merinoes weighing 103 lbs. a head, and the other some crosses between Southdowns and merinoes of the same age, weighing 220 lbs. The clip of the different lots was, he believed, in the same proportion. In one respect French sheep-farming differed very much from what was known in this country—the application of ewe milk to cheese-making. Many of the high-flavoured cheeses thus made were well known in this country. Of one variety, called Roquefort, 3,000 tons were made every year, for which quantity the milk of 250,000 ewes was necessary. A ewe would on an average give about 25 lbs. of cheese annually, on some farms fully as much as from 40 lbs. to 50 lbs. being got from a good, well-fed, well-cared-for ewe. In regard to the breeding of horses, he explained that the French Government took a paternal interest in the improvement of the stock of the country, being the possessors of some 2,500 good stallions, which were stationed at specified places, and the use of which by farmers and others was calculated to improve the class of roadsters. He also mentioned that schools existed at which instruction might be had as to the proper mode of breaking in young animals. Another peculiarity to be noted in France was the extensive use of mules and asses. In one district alone there were 28,000 of these animals, the mules bred from jack-asses and mares. The jack-asses were, he stated, kept solely for breeding purposes, and were on that account much valued, selling from £100 to £500. In their rearing of pigs the French had not made much progress by crossing; but in the breeding of rabbits, pigeons, and poultry they did wonders. Near Paris there was a large number of small farmers, holding from 10 to 20 acres, or even less, who devoted themselves to the rearing of rabbits, which were brought to a great size; and by these men a thoroughly good thing was made from the business. Pigeons, as big as poultry, were sent to market in the same way and the attention paid to poultry was indicated by this, that last year the French sold 1,000 millions of eggs, over and above what they used themselves—a sale which represented about two millions and a half of money. This latter circumstance was, he submitted, one which should be laid to heart by the farmers of this country, as any such point was in the meantime entirely neglected at home. Bee-farming was another occupation carried to much perfection in the sister country, there being in Brittany 307,000 hives, and the honey produce of the province being worth £150,000. In concluding his remarks he suggested that there might possibly be some places in this country where potatoes and corn could not be profitably grown, but where it might be well for the tenantry to give more attention to those minor branches of farming which were found to pay so well in France.—*Ayr Advertiser.*

ROOT CROPS AS FOOD AND MANURE.

AT the opening meeting for the season of the Cirencester Chamber of Agriculture, Professor Church read an interesting paper, of which the following is a portion:—All foods have to be valued, not only according to their absolute richness in the several constituents of food, but also in regard to the ratio which these constituents bear to each other. As these constituents may all be regarded as nutritive, though in different degrees, it is convenient to speak of them as nutriments. There are six:—1, water; 2, flesh-formers or nitrogenous matter or albuminoids; 3, starch, sugar, and carbohydrates; 4, oil and fat; 5, fibre; 6, mineral matter or ash. My chief object to-day is to bring before you the results of some analyses of roots which have been made by an improved process. These results mainly touch the second item of our list, flesh-formers, but they seriously alter the accepted theoretical value of roots as food by showing another kind of error in our estimates of their feeding value, an error in the ratio between this second group of nutrients, or the flesh-formers, and the third and fourth groups taken together or the heat-givers. Incidentally, I shall allude further on to the functions and uses of most, if not all, of the six groups of nutrients, but it is expedient to explain at once what is meant by this ratio in question. I shall call it the 'nutrient ratio,' and to avoid decimals shall assume that we are always dealing with 10 parts (be they grains, ounces, or pounds, or more abstract quantities), of flesh-formers (or nitrogenous compounds of vegetable origin, but like the albumen of eggs, the casein of cheese, or the fibrin of meat). If we look at those kinds of natural herbage which best sustain the health and growth of our farm animals—we look at those artificial foods which bring them to an early maturity, we shall find that the nutrient ratio shows a high proportion of flesh-formers. But the range is very extensive—from 8 to 10 in decorticated ground nut-cake to 200 to 10 in sugar-beet. The richest pasture grass will give 38 to 10, the poorest 90 to 10. We cannot fix a nutrient ratio which shall be equally adapted for all animals at all stages of the feeding process, but we can ascertain by direct experiment what ratio gives the best result in the particular circumstances of each case. To calculate the nutrient ratio we add together the percentages of starch, of sugar, and of all other nutrients of the same group, called the carbohydrates; then we multiply the percentage of oil by 2½, and include the result in the total sum of heat-givers. The percentage of flesh-formers having been ascertained by analysis, we arrive at our ratio by a simple sum of proportion. Now the chief cause of these calculated ratios being wide of the truth in the case of roots and succulent fodder plants, arises from the simple fact that it has been the habit of agricultural chemists to reckon all the nitrogen found in these foods as existing in the useful form of flesh-formers, while in reality this is not the case. On two former occasions (1873 and 1874), I pointed out this fact to the Chamber, and it has at last attracted general attention. I cannot claim the credit of discovering this fact, for Lawes and Gilbert pointed it out with distinctness in a paper read before the British Association so long ago as 1852.

FALLACIES OF ANALYSIS.

In October 1875 I announced some startling corrections of the current view obtained in 1874, but almost too startling to secure my own belief at that time. But other methods in the hands of foreign chemists having confirmed my figures, I was able to say that the mangel must be placed below the swede, and even the turnip, so far as richness in flesh-formers was concerned, the comparison being made with roots grown side by side under precisely the same conditions. My mangels showed less than one-fourth of the flesh-formers with which they would have been credited, had the ordinary process of analysis been followed. I do not mean to affirm that such a result would be invariably obtained, but subsequent experiments enable me to say that from one-third to three-fourths of the nitrogen of this root exists in forms useless for food, though excellent as manure. This fact of course obliges us to alter the nutrient ratio. To show how far the new results differ from the old, I give these numbers—

FLESH-FORMERS IN MANGELS.

Variety of root.		Water.	Flest-formers by old process.	Flesh-formers by new process.
		Per cent.	Per cent.	Per cent.
Feeding beet	...	94·0	1·432	0 63
Yellow Globe	...	93·7	1·025	0·53
Long Red	...	91·5	1·080	0·51
Golden Tankard	...	90·1	1·510	0·57

These roots were exceptionally large and watery, so that these figures must not be taken as representing the average richness of these varieties of mangels. Yet the above percentages confirm the statement that half of the assumed flesh-formers of mangels may be non-existent. Of 12 analyses published in 1876-7 of different varieties of mangels, and given in the German *Year Book of Agricultural Chemistry*, the lowest assumes 0·92 per cent. of flesh-formers, and the highest 1·75, the mean being 1·32; it is probable that this number should be halved to represent the truth.

MANURE EXPERIMENTS WITH OATS UNDER GLASS.

We have been favoured with a copy of the report of interesting experiments with different manures in the growing of oats, conducted during last season by Mr. J. Scott Dudgeon, at Longnewton Place St. Boswells. The experiments were on oats grown in pots under glass with different manures; and the report, which forms part of the annual issue of the Chemical Agricultural Association of Scotland, is certain to interest most of our readers. We give the following extracts:—

The objects of the experiments, full details regarding which are given in accompanying tables, may be roughly stated as follows: —1. To test the cheapest source of phosphorus and nitrogen. With this view coprolites and bone-ash were chosen, and these were tried in their natural state—reduced to as fine a powder as possible in a pestle and mortar; and also in their dissolved state—acted on by sulphuric acid. The first eight experiments were devoted to this object, the first four having an addition of nitrate of soda, and the last four an addition of sulphate of ammonia. The cost in each case is pretty much the same—say 2s. 6d. per acre in favour of the mineral, and the proportion of phosphorus in each almost the same—viz., 36½ per cent. where undissolved, and 24 per cent. were dissolved. Nitrate of soda and sulphate of ammonia were also tested against one another, as sources of nitrogen, the quantity in the nitrate of soda application being slightly smaller than in the sulphate of ammonia, as also is the cost—3 per cent. less in quantity of nitrogen, and 2s. 6d. per acre in cost. 2. To test an equal money value application of other light manures against those already mentioned, as well as against one another, and with this object Peruvian guano, dissolved Peruvian guano and fish guano formed the next three experiments, while another was devoted to an application of dissolved bones, with an addition of nitrate of soda at a very similar cost per acre. 3. To test the value of an addition of potash. For this purpose Nos. 13, 14, and 17 of the subjoined table were allotted. 4. To test Peruvian guano as the source of nitrogen against nitrate of soda and sulphate of ammonia. With this end in view Nos. 16 and 17 were made, and compare most directly not only with Nos. 12 and 14, but also with all the others. 5. To test the relative result from a medium application of farmyard manure, for which purpose No. 18 was added. 6. To test a plot without any manure as a comparison with all the others and so to discover what beneficial results in a remunerative sense follow.

The scene chosen for the site of the experimental house was a sheltered hollow, fully exposed to the influence of the sun, and about 500 feet above sea level. The structure erected to contain the thirty-six experimental pots was 14 feet long by 7½ feet wide, the roof sloping from 7½ feet to 6 feet high. The roof was composed of glass, in four sashes of 3½ feet wide and 8 feet long each. The enclosure was made of rough wood, boarded at top and bottom for about a foot, while the sides were formed of ¾ inch wire netting. The experiments were conducted in earthenware pots 12 inches in diameter and of the same depth, resting on boards off the ground, slates being placed beneath each, so that the roots could not penetrate into the soil beneath. The pots were placed among riddled ashes, to preserve them from drought and sun. The soil used was all taken from a field close at hand, which was cropped with oats the previous year, and is a thin poor clay. It was taken spade deep, and afterwards well mixed and riddled, and one-fourth of small stones, riddled from gravel, mixed with the soil to keep it open. In preparing the pots a depth of 2 inches of stones or gravel was put at the bottom of each pot, followed by 8 inches 'soil.' The seed oats were then deposited to the number of twenty grains in each pot, the manure sprinkled over them, and the remainder of soil added. Analyses of the manures were made before application, and the quantities accurately weighed in the laboratory in Edinburgh. There were two pots of every number; thus each experiment was made in duplicate, and arranged in relative positions in the house.

The duplicate pots of each experiment were under as dissimilar influences as possible as regards situation, one of each occupying an inside position, and the other an outside. The crop selected for the experiments was grey oats, twenty selected seeds of which were put into each pot, and the sowings were made on the 6th and 10th of April (No. 18 on 20th April). All were up, except the last sown, about the 30th April, and they were thinned out by degrees, as they seemed healthy, to ten plants each pot, the thinning being completed by the end of the first week in June. Some plants were attacked by grub or some other pest, and some pots were consequently unequally planted, and had occasionally a weak plant or two left. The plants were watered at first once each day in the evening; but during hot, dry weather they were watered twice—morning and evening. They never were soaked, being only kept moist. About the 2 th July they 'shot' out to head, some partially, others quite out, and by the 27th July *only* all were really 'shot.' Great diversity was observed in the different pots in point of earliness and lateness in shooting. The plants that grew best and looked best at first, about the beginning of July began to fall off, while those later and more backward at first began to come up to the others and promised better; notably those with applications of phosphates in the undissolved state were most backward and unpromising for long, but latterly improved in a very marked way, and when ready for the sickle appeared quite as "gifty" as those which had promised better in the earlier part of the season.

It may be interesting to reproduce a series of observations, made on the 27th of July, as to the growth and appearance of the various pots at that date, which may be compared with the results as ascertained by the scales after harvesting. Between 1 and 3, mineral dissolved and undissolved, with the addition of nitrate of soda, there was little perceptible difference. Between 2 and 4, bone-ash dissolved and undissolved, with nitrate of soda, there was again little difference, if anything in favour of the undissolved. In the case of 5 and 7, mineral dissolved and undissolved with sulphate of ammonia there was no decided difference, the dissolved in each instance being the earlier. Between 6 and 8, bone-ash dissolved and undissolved, with sulphate of ammonia, the palm might be awarded to the undissolved. In the case of 1 and 5, dissolved mineral, with nitrate of soda and with nitrate of soda and with sulphate of ammonia, there was no difference, if at all, in favour of the nitrate. Between 2 and 6, bone-ash, dissolved with nitrate of soda and with sulphate of ammonia, there was little difference, perhaps the latter had it on the whole, and in the case of the pot to the south most decidedly. No. 3, mineral and nitrate of soda against 7, mineral and sulphate of ammonia, here the nitrate was best; as was also the case in the experiment with 4 and 8, bone-ash, with nitrate of soda and with sulphate of ammonia. There was no decided difference between 9 and 10, Peruvian guano, dissolved and undissolved, both being short of some of the former applications, and both earlier. Fish guano (11), compared with Peruvian guano (9 and 10). At first the former looked very badly, and was later, but having improved, now compared similar to the latter applications. In the case of 12 and 16, dissolved bones with nitrate of soda and with Peruvian guano, it was thought that the latter would prove the better and the cheaper, indeed, from the then appearance, it seemed likely that 16 would turn out the best of the whole applications. Nos. 13, 14, and 17, which have each an addition of potash, when compared with 1, 12, and 16—the same applications without the potash—indicated no perceptible superiority. No. 15, which is credited with 'nothing,' has all along thriven well, it brairded regularly, and has continued healthy, and though weak and never strong looking, still promised better than could have been expected. The crop was cut at two different dates. On the 28th of August, Nos. 16, 14, 13, 10, 9, and 11, to the south, being fully ripe, were cut, and the others on the 4th of September—being all quite ready for the sickle, with the exception of No. 4 to the south, No. 7 to the north, and No. 11 to the north, and both pots of No. 18, which were all a little green. The same variety of oat, sown in the field in the ordinary way, on the 8th of April, was cut on the 24th of August, showing that the influence of the glass had not in the least degree forwarded the growth of those under experiment. Indeed, there was no perceptible increase of temperature inside the structure; the sides being fully open, permitted free circulation of air at all times. After being allowed thoroughly to 'win,' they were carefully thrashed out, the grain and the straw of each pot being put in separate parcels, properly numbered. And on the 30th of September these were all weighed in Mr. Falconer King's laboratory.

The following table shows the quantities and cost of manure applied per acre, and the percentage of phosphorus and nitrogen which each application contained:—

No.	Manures.	Cwts. per acre.	Cost per acre. s.	d.	Total. s.	d.	Percentage of phosphorus.	Percentage of nitrogen.
1	Mineral Superphosphate... and Nitrate of Soda ...	3·33 1·11	14 17	7 5	32	0	24·75	17·76
2	Bone Ash Superphosphate and Nitrate of Soda ..	2·66 1·11	17 17	3 5	34	8	28·14	17·76

18	Farmyard Dung (wellrotted)	156·	58	6	58	6		

Mr. Scott Dudgeon set to work with the laudable objects of testing the cheapest source of phosphorus and nitrogen, the efficacy of potash added to other manures, the comparative value of the Peruvian guano of the present day, and the superiority or otherwise of farmyard dung as a dressing for oats. The pots which got undissolved phosphates gave a better return of grain, though rather less straw, than those to which dissolved phosphates were applied, each getting a similar allowance of nitrogen. The mean of the several pots devoted to the solution of this question showed an increase of 87 bushels of grain per acre in favour of the undissolved phosphates, but the dissolved gave 1½ cwt. more straw per acre. Nitrogen having been applied along with phosphates, the above result will not astonish practical farmers.

Coming to a comparison of the pots which received their nitrogen in the shape of nitrate of soda with those getting sulphate of ammonia, we find that on the average the latter has the advantage, though not to a very large extent. The difference in favour of sulphate of ammonia is 1 cwt. of straw per acre and 1½ bushel of grain. The difference in price of the two articles was 2s. 7d. per acre, the sulphate being, of course, the dearer. Estimating the grain at 3s. per bushel, and the straw at 2s. per cwt., it will be observed that the dearer article is in the end the cheaper by about 4s. an acre. Many farmers would not have been surprised though the difference in favour of sulphate had been even greater.

The value of potash salts has been very distinctly brought out. The pots which received no potash yielded on the average 59·1 bushels grain and 27·8 cwts. straw per acre, while those which obtained about three-fourths of a cwt. of muriate of potash per acre yielded 65 bushels grain and 28·6 cwts. straw. There was thus an increase of about 6 bushels of grain and nearly 1 cwt. of straw produced by the addition of 5s. 9d. worth of potash, or a money gain of about 14s. per acre.

In reference to the source of the phosphates, the results are very interesting, and generally accord with the experience and opinion of many of the best farmers. The four pots where phosphates were derived from bone ash gave a mean of 61·9 bushels grain and 29·8 cwts. straw per acre; while those manured with phosphates from coprolites produced only 64·4 bushels grain and 26·8 cwt. straw. The superiority of bone ash is here, as on many a farm, decided, the difference being 4½ bushels of grain and 3½ cwts. of straw per acre The bone-ash phosphates cost 2s. 8d. per acre more than the other; but this additional outlay gave extra return of about 20s. per acre. This does not accord with the experiments of the Aberdeenshire Agricultural Association, only the latter have as yet been confined to turnips, which may account for the varying results. Mr. Dudgeon's conclusion in this matter will, nevertheless, substantially agree with the experience of a large number of Scottish farmers.

For several years back complaints have been frequent regarding the inferiority, or, at any rate, the variety and uncertainty, of the quality of the so-called Peruvian guano. Less than twenty years ago the Peruvian guano then obtainable formed the best top-dressing for cereals. Latterly, however, this article has deteriorated so much that confidence in it has been considerably shaken, nor will the experiments under consideration tend to strengthen that confidence. Two and two-thirds cwts. of Peruvian guano in No. 9, it will be seen, produced 55 2 bushels grain and 25·5 cwt. straw per acre, while the same quantity of dissolved Peruvian guano in No. 10 gave the worst results of all, showing only 2·6 cwts. more straw and actually 1·3 bushels less grain than were reaped from No. 15, which got no manure of any kind. No. 11, manured with fish guano, is better, but still considerably behind the produce of the pots to which the mixed artificial manures were applied.

Used along with dissolved bones, however, the Peruvian guano has done better, and beats in a substantial manner nitrate of soda. The mean of the pots manured with dissolved bones and Peruvian guano topped that of those manured with dissolved bones and nitrate of soda by 5½ cwts. straw and nearly 7 bushels grain per acre. The difference here is rather more decided than many people would have expected.

The largest return stands to the credit of good farmyard dung. No. 18 was manured with this article alone at a cost of 58s. 6d. per acre, which was by 15s. the dearest to start with, though it turned out the cheapest in the end. From the application of the farmyard dung there was a return of 80·9 bushels grain and 45·9 cwts. straw. As compared with the pots which got no manure, there was thus fully 4 qrs. grain and 25·3 cwts. straw due to less than £3 worth of dung, which indicates a handsome profit.

A comparison of the pots which indicate a profit on the application with these which show a loss as regards the percentage of phosphates and nitrogen, is interesting as bringing out the effect which the percentage of phosphates apparently has on the yield of grain. 'Those,' says Mr. Dudgeon, 'which gave a profit of above 20s. per acre, viz. Nos. 3, 4, 8, and 17, contain on an average 35 per cent. of phosphates and only 17 per cent. of nitrogen; while the pots which indicate the greater loss, viz. No. 9,10,11, and 13, contain only 17 per cent. of phosphates and nearly 21 per cent. of nitrogen.'

Mr. Dudgeon concludes his valuable report with the following observations in favour of experiments under glass:—

'That experiments can be conducted, with the hope of any good results following therefrom, on the limited scale these are being carried on, I know is questioned by many. They no doubt have their drawbacks in comparison with those conducted on a large area in the open field, but, too, they have many advantages which are apt to be overlooked, and to some of these I would draw attention. 1st. The quantity and quality of the soil used can be made exactly uniform in the case of each and every one of the series. 2d. The plants grown are confined absolutely to the portion of soil and manure allotted them. 3d. Exactly the same number of plants can be employed in each experiment, and from easy observation and judicious thinning out, &c., kept nearly uniform as far as accident or disease might affect them. 4th. The quantity of moisture can be regulated as necessary and made exactly uniform in all. 5th. They can be perfectly protected from all accident, as hail, wind, &c., as well as safe from the ravages of animals, birds, and insects. 6th. In harvesting, every portion of the produce can be secured without the slightest loss.'—*North British Agriculturist.*

GARDEN.

WATERING.—The *Gardener's Chronicle* says that in dry weather, when watering is important, it should be borne in mind that a good soaking once a week or so—a soaking that penetrates thoroughly, the water finding its way to every part of the root of the plant—is most beneficial, but that watering a little every day or so, giving homœopathic doses, is an operation much better left alone, for much more harm than good is likely to result from such a practice, in so much as watering in such quantity as to moisten the surface only causes growth of fibres near the top; the slight moisture not being sufficient to nourish them, but on the contrary, the young, tender growth of fibres being within reach of the burning sun, must result in exhaustion to the plant. Water, therefore should at all times be administered with a liberal hand, that it may soak and percolate thoroughly, as a long shower of rain will do, and the growth of roots will be produced and encouraged in their natural position, going deeper and deeper after the nourishment they effect, and will thus be enabled to withstand any occasional neglect.

BASSIA LATIFOLIA ROZEL.—The flowers are produced in enormous quantities in March and April, after the old leaves have fallen and before the new leaves have appeared; the crop rarely fails. The fleshy flowers fall off and cover the ground beneath the trees, and are gathered eagerly by the natives every morning during the flowering season; a single tree yields from 200 to 400lbs. weight of flowers. These flowers are stored as a staple article of food by the Bheels and other tribes, and so valuable do they consider these trees, that in time of war the threat of cutting them down generally reduces them to submission.

The flowers when dried have somewhat the odour and appearance of Sultana raisins. Lately examined by a French chemist, M. Petit, they were found to contain half their weight of sugar, and are therefore very nourishing.

In a paper recently read before the Linnæan Society by Mr. Lockwood, that gentleman stated that wild animals of many kinds troop eagerly to the mahwah trees during the season to feed on the flowers. He was therefore led to experiment upon domestic animals, and it was found that the flesh of pigs fed upon mahwah flowers in this country was much improved and acquired a delicate flavour. The animals so fed rapidly come into condition.

Again.—

The trees thrive in poor stony ground, and might therefore be cultivated on land not available for other crops. So regular is the yield of flowers, that it is said a bad mahwah harvest has never been known in India.

The flowers when dried will keep for almost any length of time and do not appear to be attacked by insects.

From the seeds an oil is extracted by the natives; it is used for lighting purposes and for soap-making. The smoke arising from the burning of the oil-cake, after expression of the oil, is said to be poisonous to rats, &c.

The mahwah tree, then, affords a means of obtaining an almost unlimited supply of food, both for man and beast, a food which will keep a great length of time in any natural temperature, and which requires no trouble to procure and no outlay in cultivation, The tree readily propagated itself by seed which, in India, is usually self-sown.

THE PROPOSED BOTANIC GARDEN AT GANESH KHIND.

GOVERNMENT RESOLUTION.

DURING August 1878 the attention of the Government of Bombay, was given to the formation of a botanic garden at Ganesh Khind, near Poona. The questions thereto pertaining were referred to a committee of specially selected and highly qualified officers; namely:—Colonel Palin, Mr. Shuttleworth, Dr. Gray, and Major Mant, R.E. Besides the matters pertaining to the Ganesh Khind Garden, the Committee's consideration was invited to the question whether Poona or Bombay should be chosen as the place for the principal botanic garden of the Bombay Presidency.

2. After much enquiry and consideration the Committee deem Poona to be, on the whole, the best place for this important institution. They submit an elaborate and interesting report, and sum up their recommendations under eighteen heads. These recommendations are all highly

approved by the Government of Bombay, with the intention of carrying them out whenever financial means shall permit. Some of them must, for want of available resources, stand over for the present. Some of them, however, may be sanctioned now, as given below, namely:—That on the present site at Ganesh Khind be established the chief botanic garden of the Bombay Presidency, and that its extent be forty acres or thereabouts. That a small branch garden, consisting of four or five acres, be established in Bombay, and that the Grant College compound be selected for this purpose. That the Superintendent be relieved of his present incongruous duties of oil-presser and drug-manufacturer, and that the oil and pharmaceutical apparatus be transferred to the Medical Stores. That part of the garden-house thus vacated be fitted up as a library and class-room; and that certain selected botanical books and diagrams be purchased. That a complete standard herbarium of the indigenous plants of Western India be formed, and that it be kept permanently in the garden house at Ganesh Khind; certain rooms therein being fitted up for the purpose. That the main scientific garden be laid out in the irregular picturesque style, with special reference to landscape effect; and that the planting of the garden be carried out gradually and without any undue haste. That the chief resources of the garden be devoted to the bringing together of the indigenous plants of Western India, and that, until this is satisfactorily accomplished, no pains be taken, except in special cases, to introduce foreign plant. That the details of planting and leaving out of the scientific garden be left in the hands of the present superintendent. That the system of interchange with other botanical gardens, of seeds and living plants, be developed to as great an extent as possible. In these and other respects the services of the present superintendent, Mr. Woodrow, will be most useful.

3. The cordial thanks of the Governor in Council are tendered to the President and Members of the Committee for the able manner—a manner which is at once learned, practical and scientific—whereby they have carried out the interesting and important task entrusted to them. His Excellency in Council trusts that their labours will bear fruit hereafter for the advancement of botanic science in Western India.

4. The acknowledgments of Government are also offered to Colonel Laughton and to Colonel Goodfellow, R.E, for the assistance rendered by them to the Committee in the preparation of surveys, plans and estimates.

MINUTE BY H. E. THE GOVERNOR.

I would invite the attention of my honourable colleagues to the status of the botanic garden on the left bank of the river Mula near Ganesh Khind. Apparently this garden must be called botanic, though its condition botanically is far from being adequately developed.

2. It appears to have been established primarily for producing medicinal plants, which would supply to the Medical Department of Government, what are termed "country medicines," that is, medicines indigenous to India. In this way it was to prove remunerative, from the value of the medical stores to be thus provided. And this object is in some degree attained.

3. But, as it was placed under the charge of a professional and scientific gardener, trained in England, Mr. Woodrow, the garden has gradually acquired a botanical character. Many useful, rare, foreign, ornamental trees, shrubs, and plants, have been planted and are being planted there year by year, which are not at all medicinal. Specimens are multiplied, and many of them are sold or offered for sale to the public. It is very creditable to Mr. Woodrow that he should have accomplished all this notwithstanding the more particular and obligatory purposes which the garden has had to fulfil.

4. The result, however, manifestly is that the garden has the appearance of being an undeveloped and poorly kept Botanic Garden—a garden which from that point of view is not worthy either of this Government or of this Presidency. The attention of every visitor must naturally be attracted to this patent circumstance rather than to the fact (ascertainable only by enquiry), that the garden is not exactly botanic, but has merely a subsidiary botanical branch attached to the main body of the affair, which is the production of indigenous medicines. This state of things cannot be satisfactory to any one concerned, and I think my colleagues will concur with me in thinking that the position is not one which we should wish to see perpetuated.

5. As we have no botanic garden in this Presidency, I suggest that we avail ourselves of this opportunity of establishing one by making this garden avowedly a botanic garden; so many plants and trees, being already available. The situation, too, as regards soil and moisture, being all that could be desired, being close to the great station and city of Poona, with all its institutions, educational and other, also being under the eye of the Government and its staff for several months of each year. It would not be necessary to incur any considerable expense at first. Once the garden was recognized as botanic, additions would be made to it from time to time. But the scientific branch of it and the cost connected therewith would have to be separated financially from the medicinal or directly remunerative branch. It is impossible that the scientific branch should pay itself: it must involve some expense, however moderate.

6. I propose that a Committee be appointed of experts to examine the garden and to propose detailed measures for forming a botanic garden here, at the least possible cost. Such Committee might consist of Dr. Wellington Gray, Secretary to the Surgeon-General (an officer well known for his attainments in botany as in other sciences), Colonel Palin, Bombay Native Infantry (also well known for his interest in and knowledge of botany), and Mr. A. T. Shuttleworth, Conservator of Forests.

7. Every assistance will doubtless be afforded to the Committee by Mr. Woodrow.

RICHARD TEMPLE.

THE COMMITTEE'S REPORT.

In accordance with Government Resolution No. 2577, dated 30th of August, 1878, the Committee named therein met for the first time at Ganesh Khind Garden, on the 8th of September, and proceeded to consider the measures necessary for forming this into a scientific botanic garden.

At their preliminary inspection the Committee were most favourably impressed with the situation and general aspect of the grounds and the character of the soil, and they then formed an opinion which, subsequent and more familiar acquaintance with the place has served to confirm, that natural advantages, which the present garden possesses, render it an eminently suitable site for the establishment of the chief botanic garden of this Presidency. The undulating surface permits of the garden being laid out with due consideration for the landscape effect, the soil is good, almost throughout, and is well adapted to the growth of the great majority of our indigenous plants; the climate is also suitable; the supply of water appears to be abundant and perennial; and, lastly, the position of the garden with respect to the city of Poona and its educational institutions is all that can be desired.

The Committee apprehend that the only objection, which can be raised against placing the chief botanic garden of Western India in the Deccan lies in the distance of the garden from the great centre, and the educational and scientific institutions of Bombay. The fact of the easy accessibility of Poona, however, will in a certain measure overcome this objection. As a rule, a large botanic garden, established for scientific objects, should be as close to the metropolis as possible, and could a suitable site be obtained for the purpose near Bombay, the greater desirability of such an arrangement, as compared with the proposed one would doubtless be admitted. But as the Committee are aware that no sufficiently large space of ground combining within itself the necessary capabilities as regards situation, soil, and water-supply exists in the vicinity of Bombay, they agree in recommending that, for reasons already stated, the principal scientific garden of Western India be established at Ganesh Khind.

It is manifest, however, that the Deccan is unsuited for the growth of certain tropical plants which require a greater degree of atmospheric moisture, and a more constant high temperature than the climate of the Deccan affords. Many of our indigenous, and a large number of naturalised plants can only be grown with difficulty above the Ghats; and in some cases hardly at all. They require the moister, warmer, and more equable climate of the Konkan. For the growth and propagation of such tropical plants, therefore, as will not flourish in the Deccan, the Committee would suggest the advisability of forming a small branch garden near Bombay. This need not consist of more than four or five acres, and the Committee are given to understand that the compound surrounding the Grant Medical College is sufficiently well adapted for the purpose they have indicated. The soil is fairly good, but in parts the ground is at so low a level as to be under water during heavy rains. Close by, however, a sufficient supply of earth exists, which could easily be utilised for raising the land to a proper level. The Grant College compound possesses one chief advantage, i.e., that it is in the immediate vicinity of the Medical School, and, were a scientific garden established here, it would be more largely used to encourage the spread of botanical knowledge than if it existed elsewhere. The Victoria Gardens were, as the Committee are informed, originally intended for a botanic garden in connection with the Victoria and Albert Museum; but for several years past they have not been conducted with any scientific object—merely as a pleasure garden. It is possible that a small portion of these gardens might be obtained for the Konkan branch garden, but for certain reasons, which need not be here specified, relating to their past and present financial position and the mode in which they are managed by the Municipality of Bombay, the Committee agree in thinking that the establishment of the branch garden in this locality would prove an unsatisfactory arrangement. The soil, too, of the Victoria Gardens is more or less saline and not well fitted for the growth of trees or shrubs. The Committee are therefore decidedly in favour of the Grant College compound being converted into the branch garden. The cost of this portion of the general scheme will doubtless form the subject of a separate investigation.

The Committee now proceed to set forth in detail the measures they would recommend for forming a botanic garden at Ganesh Khind and for keeping it up in the best and most economical manner possible. They consider that a space of forty acres, or thereabouts, out of the sixty-five which the entire garden is said to contain, is amply sufficient for the scientific garden, and this, if properly laid out and fully stocked, they think is quite as much as can be conveniently managed. The Committee propose, therefore, that that portion of the estate to the east of the nulla, and known on the plan as laid out, be the botanic garden, the remainder being reserved for the cultivation of medicinal plants and for miscellaneous agricultural purposes.

* * * * * * * *

The formation of a complete herbarium of the indigenous plants of Western India, would supply a want which has long been felt, and frequently deplored, and would prove of great scientific and practical value. A general Indian herbarium being already established at Calcutta, the Committee are of opinion that the proposed herbarium at Ganesh Khind should consist only of our indigenous plants. A separate collection of all the useful plants

cultivated in this Presidency, both indigenous and non-indigenous, should also be formed.

The Committee agree that the standard herbarium should be kept at Ganesh Khind, as the extremely moist climate of the Konkan during the rains affects dried plants most injuriously. A small branch herbarium might be established in Bombay in the Victoria and Albert Museum, and, when necessary, plants could from time to time be transferred thither from Ganesh Khind. Valuable or rare specimens should not, however, be allowed to leave the latter place, except during the dry season. The collection and preparation of a herbarium is a comparatively inexpensive process; the cost of collecting might be charged under travelling expenses, and of preparing and arranging the plants, to contingencies. Local botanists, too, and the Forest Department, would no doubt be glad to assist and contribute.

. . . .

To carry on the ordinary duties of the scientific garden a permanent establishment, in addition to the present superintendent and the office clerk, will be required. This should consist of at least thirty-five professional *malees* and a *muccadum*. For rough labour, coolies can be employed when necessary, with boys or women for weeding. A herbarium-keeper and draftsman is also essential, and a person competent for the duty can be obtained for Rs. 60 per mensem.

The annual cost of a permanent garden establishment such as that indicated above will be as follows :—

	Rs.
Superintendent at Rs. 350 per mensem	4,200
Office clerk at Rs. 25	300
Herbarium-keeper and Draftsman at Rs. 60 ...	720
Malleys and Muccadam at Rs. 300	3,600
	8,820

To the above must be added—

		Rs.
Travelling allowance	...	400
Library allowance	...	100
Herbarium	...	20
Office contingencies	...	120
Garden contingencies.	Annual Repairs	250
	Purchase and repair of implements	100
	Flower seeds	50
	Pots	40
	Packing and carriage of plants and seeds	100
	Coolie labour	7[illegible]
	Cattle food (grain)	[illegible]
	Manure ...	1[illegible]
	Miscellaneous	120
		Rs. 2,980

It will thus be seen that the estimated annual expenditure necessary for maintaining the garden in a state of proper order and efficiency amounts to Rs. 11,800, or in round numbers Rs. 12,000. This estimate the Committee have no hesitation in characterising as an exceedingly moderate one. As a set off against it, moreover, there is little doubt that by a judicious course of management a very considerable income will eventually be derived from the sale of plants, seeds, miscellaneous garden produce, and herbarium specimens. The present receipts from the first three of these sources amount to about Rs. 1,500 annually.

The Committee having now considered and discussed fully the steps which in their opinion are necessary to the formation of a scientific botanic garden at Ganesh Khind, it will be convenient to set forth here a summary of their recommendations :—1. That on the present site at Ganesh Khind be established the chief botanic garden of the Bombay Presidency, and that its extent be forty acres or thereabouts. 2. That a small branch garden, consisting of four or five acres, be established in Bombay, and that the Grant College compound be selected for this purpose. 3. That all the main roads of the Ganesh Khind Garden, as shown in the plan, be permanently constructed by the Public Works Department at as early a date as practicable. 4. That a piece of ornamental water be formed; this work to be also undertaken by the Public Works Department. 5. That an orchid and fern-house, a summer house, a cattle and implement shed, and a potting shed be erected, and that the existing plant-house be reconstructed; all being done by the Public Works Department. 6. That the water-supply system of the garden be of iron piping, with masonry tanks or hydrants at intervals. 7. That the superintendent be relieved of his present incongruous duties of oil-presser, and drug-manufacturer, and that the oil and pharmaceutical apparatus be transferred to the Medical Stores. 8. That part of the garden-house thus vacated be fitted up as a library and class room, and that certain selected botanical books and diagrams be purchased. 9. That a complete standard herbarium of the indigenous plants of Western India be formed, and that it be kept permanently in the garden house at Ganesh Khind, certain rooms therein being fitted up for the purpose. 10. That the main scientific garden be laid out in the irregular picturesque style, with special reference to landscape effect; and that the planting of the garden be carried out gradually, and without any undue haste. 11. That the chief resources of the garden be devoted to the bringing together of the indigenous plants of Western India, and that until this is satisfactorily accomplished, no pains be taken, except in special cases, to introduce foreign plants. 12. That a small class garden, for practical instruction in elementary systematic botany, be established. 13. That the [illegible] of the planting and laying out of the scientific garden be left in the hands of the present superintendent. 14. That for the purpose of collecting plants and specimens, the garden superintendent be permitted to travel through certain parts of the Presidency each year. 15. That the system of interchange with other botanical gardens of seeds and living plants, be developed to as great an extent as possible. 16. That a permanent establishment, consisting of a superintendent, an office clerk, a herbarium-keeper and draftsman, thirty-five *mallees*, and a *muccadum*, be entertained for carrying on the ordinary duties of the garden. 17. That an extraordinary expenditure of Rs. 22,037 be sanctioned for the purpose of constructing roads and foot-paths, excavating a pond, erecting houses and sheds providing iron piping, &c., &c., for water-supply, fitting up rooms for the herbarium, library and class-room and for the purchase of botanical books and diagrams. 18. That a recurring annual grant of at least Rs. 12,000 be provided for the maintenance of garden, herbarium and library.

The Committee desire to acknowledge the aid they have received from Colonel Laughton in the preparation of a plan of the garden and from Colonel Goodfellow, R E., in furnishing the annexed estimate. They have also to thank Mr. Woodrow, the Superintendent, for his cordial and intelligent co-operation and assistance.

In conclusion, the Committee trust that the proposals they have adopted, and which, after careful consideration, they agree in recommending as the best fitted to attain the object in view, will meet with the approval of Government, and that the result will be creation of a scientific botanic garden which shall prove second to none in this country.

CHARLES PALIN, President.
ALLEN SHUTTLEWORTH, Conservator of Forests, N. D.
W. GRAY, Surgeon-Major,
CHARLES MANT, Major, R. E.
} Members.

FORESTRY.

THE EUCALYPTUS IN ALGERIA.—The establishment of plantations of *Eucalyptus* in certain Algerian plains, hitherto innocent of trees, has been followed by unforeseen consequences of vital importance to many of the colonists. For, besides their vaunted beneficial action in purifying the air and moderating the heat, these plantations have had the further effect of attracting countless myriads of sparrows, whose depredations have reached a point of very grave severity.

THE following is from the Forest Reserve Commission's Report on the Nilgiri District to the Madras Government.—

"Without considering the possible effect of trees on rainfall and climate, we have considered as beyond dispute the facts that woodlands exercise a most beneficial effect in the retention of water and the regulation of the supply, and that any extensive denudation near the sources or along the courses of streams must of necessity be followed by destructive floods and equally fatal droughts."

A MONTH or two before his sad end, Mr. Nepean found a species of *Vanilla* vine growing in the Upper Thoungyeen forests. British Burma possesses two varieties of this plant, one with large and the other with small leaf. What Mr. Nepean saw was of the former kind, slightly resembling the true *Vanilla* which has a very narrow and somewhat short leaf and short interpetiolary joints. The specimen referred to was both in fruit and flower, a very rare occurrence as it needs manipulation to fertilize the stigma.

Mr. Hardinge, Secretary to the local Agri-Horticultural Society, found the common *Vanilla* abundant in the Arakan Hills.

SOME fine plants sent from the Upper Thoungyeen forests, to the garden of the Agri-Horticultural Society here, are said to be doing very well. The experiment of growing them amongst teak has been commenced in the East Salween Forest sub-division.

IN the *Journal of Botany* for November 1878, a new oak from Assam is described by Dr. Hance under the name of *Quercus Kurzii*. Dr. Hance says :—

At the close of the summer of 1877, just before leaving Calcutta for Penang, where he was prematurely cut off in the prime of life, that indefatigable and conscientious botanist, the late Mr. Sulpiz Kurz, sent me a few Indian oaks for examination. The only novelty in the very small collection was a curious species, ticketed in pencil, in Mr. Kurz's autograph, "*Castanea semicristata*, Kurz."

THE DIFFICULTIES OF TREE PLANTING.

"FLOREAT ARBOR" writes:—The short but pertinent article in the *Madras Times* of the 23rd ultimo, headed as above, has set me thinking. How few men there are now-a-days who care for tree-planting in any way! But how many there are whose proclivities run directly towards destroying and cutting down trees! Officials in charge of roads, and Municipal authorities too often exhibit great apathy towards the planting and maintenance of trees, and the tenant of a house having a well-planted compound will too often cut down valuable or useful fruit and shade trees just 'to let in the air' or to 'expand the view,' or will quietly sit down and see the servants destroying the trees in their search after fruit or firewood, or witness, with unconcern, the trees and shrubs ruthlessly and needlessly destroyed, by the wanton admission, or unauthorized intrusion, of cattle or goats. The native, the ryot, the herdsman, and the cooly are in most cases perfectly callous as to the fate of trees, young or old, so long as his cows, buffaloes and goats get their daily quantum of food orn from the branches, and also provided that he himself is well supplied with firewood *gratis*, to say nothing of the injury to trees caused by the pernicious habit the ryots have of annually stripping the trees of their living branches and leaves for the sake of manuring their paddy-fields! Goats, indeed, are too often the curse of this country as regards the vegetation they destroy, especially in and about our towns, villages and cantonments. They will attack, tearing and biting, anything green they may come across, if they will not eat everything, even the "milk hedge." Whatever they bite either dies or flags at once. We are told that after the introduction of goats into St. Helena they soon completely exterminated a valuable species of tree by browsing on it, and, no doubt, they would soon convert this 'happy smiling land' (botanically) into a howling "wilderness" were they only a little more numerous and a little more uncontrolled. As instances of successful planting, look at the old topes—now alas but few all over the country. Look at the old roads alongside, or crossing, the line of railway, very often so carefully lined with trees, green trees on each side. Look at the green topes, and shady roads in Mysore and look at the Cubbon Park in Bangalore. But, on the other hand, look at the failure of the planting along the "Ride" at Bangalore and some of the roads and open places that were so carefully attended to during the time of Colonel Mesham, the D. A. Q. M. G. there for so long. Of late, their fences have been broken down, and they have been eaten up, or torn to pieces by goats, buffaloes, &c., whether 'by your leave' or not is unknown. Want of water, too, is another cause of failure. Perhaps the 'famine time' may be somewhat to blame, but it is now time to take the matter in hand once more. Bellary, also, which has a few years ago been pretty successfully planted (in the cantonment) under the Municipality and A.Q.M.G. has suffered very much from the famine (*i. e.* from the drought) and scarcity of forage,—many, very many. trees and shrubs having quite disappeared. The compounds are for the most part 'all open,' and cows, buffaloes, and goats roam everywhere, day and night, without saying "by your leave," and work their wicked will.

The military regulations regarding cantonments say that "Trees should be planted about cantonments on the sides of the roads and in the vicinity of the barracks, to afford shade" * * * "Trees already planted are to be carefully looked after. The expense incurred in carrying out these measures should be met out of the cantonment funds." This is a very excellent order and should be acted up to both in the letter and the spirit no doubt, whenever there is money in hand. Many of our stations have been much 'improved' of late years. But it is time that serious attention was now paid to the planting of fuel reserves in the neighbourhood of our towns, cantonments and villages. The area of the circle cleared by the wood-cutter is increasing every year, the price of firewood increasing in consequence, and yet no attempts at replanting are made, nor have the jungles any chance of recovering themselves, the young shoots of the sprouting stumps and young seedlings being constantly eaten down by roaming cattle and goats, or destroyed by fire. It is now time to limit, at the least, cutting of firewood to a fixed distance beyond a certain radius, say seven miles from our large towns and cantonments. This would give some small chance of recovery. The Babool tree, *Acacia Arabica* (The *Gum Arabic* tree) and its relative *A. Vera* (the *true* acacia or *gum acacia* tree) which are so hard, and grow so easily everywhere might be largely disseminated by seeds from the Ceded and Southern Districts. But, perhaps, better than all others, as a fuel and generally useful wood, is that of the casuarina—now so widely spread and well known everywhere, not only as a good wood for fuel, but also as a very superior wood for general purposes, house-building, &c. This wood has been proved to stand successfully a more severe cross strain than any other wood, I believe (*see reports of Juries of Great Exhibition* of '51), whilst at the same time it is more elastic than teak, and quite as impervious to the attacks of white ants, &c., when properly seasoned. Its cost is as nothing when compared to that of teak, angell wood, &c. The jak and angell wood trees should also be more extensively planted than they are, as also tamarind (a slow grower) and jungle almond (turmanilia). But careful planting at first requires always some expenditure of time, and too often a certain expenditure of money, and afterwards a positively certain expenditure of money in watering and guarding the young trees,—expenditures which, at present, the Government is unable, and individuals have been unwilling, to incur on a large scale. The well-to-do native landholders and merchants might do a great deal in this respect if they would, and this would be just as good and proper an exercise of "charity" as feeding Brahmins and dosing the ants on the roadside with sugar.

TREE PLANTING IN AMERICA.

THE Americans are wiser than we are in the matter of tree planting, though the need for verdure is not so great in "the States" as it is in Southern India. Could not the Government of Madras take some active steps towards the reboisement of the country after the manner described in a paragraph we shall immediately quote? We think a similar course might be adopted in this country, if anybody was sufficiently in earnest to care about the matter. A correspondent of *The Times* has been visiting the State of Nebraska after an interval of ten years. This is what he says about the planting of trees and the manner in which such planting is fostered by the "free" Government of the United States:—"The sight of a tree is no longer rare or noteworthy. The prospect is now varied and rendered attractive by numbers of snug farm houses and by frequent clumps of trees. A farmer's first care after preparing land for the plough, is to plant trees on his homestead; they grow rapidly, and they serve the purpose both of supplying the timber which is much needed, and also the protection from the winds which is specially desirable. Even if self-interest did not prompt the farmer to do in Nebraska what Scott did with such good effect around Abbotsford, he has another inducement to help in covering the land with wood. A State law gives special encouragement to timber growing, taxes being remitted in proportion to the number of acres upon which trees have been planted. In proof of the rapidity with which the monotonous prairie can be diversified with trees, I may state that here the useful cotton-wood tree attains a diameter of 20 inches within the space of 12 years, that within three years after planting cotton-wood, maple, ash, and walnut trees become large enough to supply fuel, and that they furnish all the wood for use on a farm within five years after planting. Nebraska has the credit of being the first prairie State which has passed a wise law on this important subject." Our Government professes to be "paternal" we wish it would display a little paternal care towards a matter of so much importance as is the re-covering of the country with trees.

TREE-PLANTING IN SOUTHERN INDIA.

A VALUED and experienced contributor writes:—

"I read a very sensible article in the *Madras Times* to hand this morning regarding tree planting; it is one which will benefit the country at large, but to which Government give little heed and less encouragement. I can speak from experience in the Mysore province that there are large tracts of land which might be well utilised for growing trees, land which, under ordinary conditions will never yield a pie of revenue, and which native ryots will never dream of taking up for grain-cultivation, but in the hands of enterprising Europeans who would take trouble and lay out capital, might be brought into use as fuel preserves.

"But what encouragement is held out to such individuals? None. On the land being surveyed and assessed, if an application is made for a vacant site, Government insists on the full assessment being paid, and no reduction whatever is made. Some years ago, I believe in Mr. Bowring's time, there were some rules drawn up, under which parties might apply for waste land to plant out with fuel trees. Such lands were given free of assessment for a period of ten or fifteen years, subject to conditions which allowed Government to resume the lands if required for public purposes, of course compensating the grower, and, further, ascertain what proportion of area was to be planted yearly. The rules, however, did not *draw*, as the officials placed a good many obstacles in the way, giving all kinds of trouble and petty annoyances; and, finally the Government rules have been allowed to become a dead letter and were then cancelled.

"Now I (and several others) who take a look well a-head know that *fuel* will always pay so long as there are railways in India, and I should like to go into the planting speculation largely, but how can I afford to pay, say Rs. 300 for 200 acres for five or six years, without getting a return. A ryot takes up land and cultivates; he has a return *at once*, *i.e.*, in the course of the year, and he is enabled to pay assessment; but with tree-planting it is different. There would be no return for at least five years, and, therefore, the next three or four afterwards that came in would only pay working expenses.

"Now, if Government would give land free for ten years, it would be some encouragement, I don't ask that Government should give *good land*, but there are hundreds of acres of waste, which

grow nought but coarse grass and broom straws, that could be well utilised. Then there are the beds of old breached tanks; some I know are cultivated occasionally, but that is only in exceptional instances, and probably occurs when the tank is situated adjacent to a large and populous village, but for every one such there are ten that are unproductive of a cent to Government. Why should not these be planted out?

"Just instance what was done in former days. If a man planted a couple of hundred trees as avenue trees along a road and round them, he was rewarded with lands free of tax, which, in after years, as a jaghire or jodi, passed into his family as valuable property. Avenue planting was good for travellers, and in some parts yielded a small revenue from fruit, but there was better benefit to the country. Now tree-planting, as you suggest, would be useful, and yet a man is not encouraged to do this. Why? Government ought to take the matter up and act in a more liberal spirit. It may be said that Government, having a large Forest Department to conserve and plant trees, do not care to encourage private individuals. This is moonshine. The Forest Department has done but little more than adopt steps to take care of *trees when they are found growing natural, i e.*, in large forests, on hills, &c., but their efforts to plant out new plantations have been very poor compared with their outlay. But the Forest Department would not be interfered, with in any way, and the efforts of private individuals would be turned to planting tracts in *maidan* places where the Forest Department would not put down a sapling.

"I may add here that a good deal of jealousy and obstructiveness to private enterprise is shewn by the Forest Department, inasmuch as, when a person applied (formerly) for a piece of land under the Forest rules, it being referred to the Forest Department, was at once reported on as being 'necessary for the operations of the Department.' Of course, this was an excuse not to give it, and it is superfluous to add that many sites so applied for have never to this day been utilised."

BRITISH BURMA FOREST REPORTS FOR THE YEAR 1877-78.

THERE has been, again, unusual delay in the submission of these reports in their completed state, owing to repeated references between the Department and the Comptroller-General, Calcutta, in regard to the financial results of the year. The report for the Tenasserim circle was received by the Chief Commissioner in manuscript as far back as 10th July, but on the 31st of that month, it was intimated that alterations in certain of the figured statements would probably have to be made. In the case of the Pegu circle, the financial statement (form 51) was received by the Additional Conservator on 26th September from the Comptroller General, and the report reached the Secretariat on 12th October.

No legislative measures were carried into effect during the year. The question of having a new Forest Act for British Burma was under consideration, as was also that of revised rules for the control of rivers and timber in transit and the management of timber-revenue stations, but no decision had been arrived at when the year closed.

In the Tenasserim circle, the progress made with reserves has not been great, and not such as might have been looked for from the report of the year previous. In the report for 1876-77, it was stated that proposals had been submitted for reserving 47 square miles, and were about to be submitted for the reservation of an area of about 170 square miles, the necessary surveys and maps having been completed. At the close of 1877-78, however, the additional area of reserves amounted only to 68 square miles. The work as regards the larger area has apparently been done over again by the Forest Settlement Department, which commenced work for the first time in the Tenasserim circle, and submitted proposals for fresh reserves containing an area of about 170 square miles. The preliminary survey and selection of tracts suitable for reserves was unfortunately delayed by the illness of the officer deputed for this duty, and an area of only about 55 square miles has been selected.

For the Pegu circle, the figures relating to sanctioned reserves, as given in the body of the report, differ considerably from those which appear in statement No. 45. In the report, the Conservator has given not only the results of the work done during the year, but also of that which has been done since the close of the year and up to what he calls the end of the season. The report however is for the official year, and should relate only to work done during that period. It only tends to confusion to mix up the figures of work done since the close of the year, which figures will again appear in the next year's report. The area of reserves added during the year amounts to 239 square miles, while it has been necessary to exclude an area of 296 square miles from that hitherto shewn under the head of "State reserves," owing to the tracts in question having been taken up under rules, which have never been sanctioned, so that the net result during the year gives a decrease of 58 square miles. The area of proposed reserves awaiting sanction at the close of the year was no less than 863 square miles. It is open to doubt whether the reservation of these large tracts does not in some cases press with some hardship on the Karens and the sparse population in the forests, notwithstanding the careful inquiry usually made into their claims and rights.

In three reserves of the Tenasserim circle—namely, Sinzway, Oankangyee, and Dalee—the propagation of teak by the Karens under the *toungya* system resulted in the cultivation of 84 acres covered with 26,465 plants, the average number of plants per acre varying, according to the locality, from 287 to 335. The experiment made by Mr. Bingham in the previous year, of sowing teak seed in lines 20 feet apart within the Sinzway reserve, was thwarted by the scarcity of labour at the proper time for weeding the undergrowth, and by the fickle disposition of the Karens. Operations were however renewed in the year under report, measures having been adopted to have labourers on the spot when they were needed, and it is expected that a satisfactory growth of healthy teak plants will be the result. Considerable progress was also made in laying down teak seed in the *toungya* clearances in the Tharrawaddy reserves, 203 acres having been sown by the Karen cultivator during the year, at a cost to the Department of Rs. 690, or Rs. 3-6 an acre, resulting in the appearance of some 77,000 healthy plants. Eight acres were sown in the same way in the Yaynay reserve of the Sittang division, at a cost of Rs. 102, and the ground is now well covered with young plants. This system is capable of very extensive development, and more scope will be afforded for it when the prohibition against the girdling of mature teak trees has been removed, and when the fire protection measures have had time to be well tested in the younger reserves. Re-production of teak by the process of "dibbling in" was again freely tried in fire-traced reserves, some 2,000 acres having been so treated in the Mokkha Beeling and Kangyee reserves of the Tharrawaddy division during the year; while the area that failed in 1876-77 was re-sown. A satisfactory growth of plants has resulted, but the process is costly, the outlay having been for the year Rs. 3,890, exclusive altogether of the expenditure in weeding and keeping down the undergrowth which springs up so rapidly as to choke the young plants. If more confidence could be placed in the real desire of the Karen cultivators to prevent fires in their grounds, the *toungya* system will very probably be found, as Mr. Ribbentrop observes, to be preferable to the other on every score, provided labourers can be secured in sufficient numbers to carry it out.

There are in the Tenasserim circle three small teak plantations, formed in 1856, and aggregating 17 acres. These have cost from first to last Rs. 22,291, but, beyond a remark that one of them (Thinganee noung) "had to be abandoned" during the year "for want of labour and owing to sickness among coolies," no allusion is made to them in Major Seaton's report, nor was any new plantation work carried out. The plantations in Pegu now aggregate 3,322 acres, the principal ones being those at Kyetpyoogan and Magayee in the Rangoon district, the enormous cost of both of which and the best means of redeeming at least a part of it are now under discussion. To the latter, 273 acres of teak cultivation were added during the year under notice, and 63½ acres cleared for cultivation in 1878-79, the entire outlay for the year being Rs 18,373. This brings up the area of the plantation to 1,306 acres, and the expenditure from first to last to Rs. 93,947. An unsatisfactory feature in the case of both plantations is their liability to injure by fire year after year. In the case of Magayee, however, which now forms a part of the newly-sanctioned Magayee reserve of 20 square miles, it is natural to look in future for greater immunity from this danger, provided a fire-trace of liberal breadth is formed around the boundary of the reserve.

In the Tenasserim circle, no minor cultivation of any kind was attempted, and the report is silent as to the progress made in that reported on in the previous year; but at Magayee, plants of *Ficus elastica* were planted out over an area of 87 acres. A portion of these however and also nearly one-third of the plants of *Chironessia esculenta* laid down in previous years perished in the third outbreak of fire in the plantation towards the end of the dry season. In the cinchona plantation at Thandoungyee, the expenditure is certainly not compensated for by the results attained. This had already attracted the attention of the Government of India, but it will now be reduced by Rs. 1,200 a year, as five Karen apprentices, who received Rs. 20 a month each, have left the plantation, where there was insufficient occupation for them, and as they were unwilling, it is said, to work in other parts of the district. The cinchona seedlings, put down in previous years, of the *Condaminea* variety, have gradually died off, and very few of them now remain. A quantity of bark was gathered from decaying and unhealthy looking trees during the year, and made over to the medical authorities for use in hospitals, but no report on its medicinal value has yet been received. A large number of seedlings of the *Succirubra* variety, and some of *Calisaya*, were planted during the year.

None of these now exist either in Pegu or Tenasserim. In the latter circle, however, a number of 30 years' permits (21) were granted in 1865, authorizing the holders of them to cut teak in the Attaran forests. They are restricted, however, to trees girthing 7½ feet at 6 feet from the ground and have to pay duty in the ordinary way on what they remove. In 1896, the rights in these forests will revert absolutely to Government. One lease also exists in the Attaran district, which was granted in 1829 for 99 years.

These, under the orders of the Government of India, continued in abeyance throughout the year in both circles, and the entire energies of the Forest Staff were concentrated on the selection and settlement of reserves.

Several practical difficulties were encountered in connection with the working of notification Nos. 33 and 81 of 8th March 1876,—some Civil Officers putting too liberal an interpretation on the scope and applicability of free permits. To correct any misapprehension on this point, revised rules were issued in January 1878, restricting the grant of free permits to persons living within five miles of the spot where the timber was growing,

and that use for their domestic or agricultural requirements only. There can be little doubt that previously much timber, really wanted for purposes of trade, had been obtained under the cloak of free permits by many persons living at long distances from the forests. Free permits of the reserved sorts of timber continued, under the revised rules, to be made for building Burmese monastic schools, rest-houses, bridges, &c. It was considered advisable in August 1877 to withdraw the right of Civil Officers to grant trade permits for the cutting of padouk. There is a very limited growth of this timber, its reputation as a durable and valuable wood is increasing, and it was thought better to leave its extraction (for the present at all events) under the control of the Forest Department. One result of this restriction will doubtless be to lead the people to the use of many varieties of unreserved timber hitherto untried, but probably equally suitable for many of their wants. Much experience has now been gained of the working of the notifications 33 and 34, of 8th March 1876, and it will be possible, in re-casting the rules, to make valuable use of that experience in so far as it will help to settle on a just and satisfactory footing the ancient forest privileges of the communities affected by them.

In the Tenasserim circle, only 174 tons of padouk, thitka, and pine were extracted by Government agency,—the dull condition of the market, added to the stock remaining over from the previous year, giving little inducement to bring out a large quantity. At Tavoy, 863 pynkadoe sleepers were ready for transport to Moulmein at the close of the year, and contracts were entered into for 6,000 more at Tavoy, and for 800 of various kinds at Mergui. In the Pegu circle 2,918 tons of various woods were extracted by the Department during the year.

Salving operations were not so successful on the Salween as in the previous year, only 4,881 logs of teak having been salved, as compared with 6,715 in 1876-77. This was due to the unusually flooded state of the river, which rendered the work one of much danger, a good deal of timber drifting out to sea. In the Pegu circle, 9,186 logs were salved, 7,980 of them being, however, delivered to claimants afterwards, compared with 1,815 restored on the Tenasserim side; but the aggregate result of the operations in both circles would appear to have been Rs. 68,950 in the form of receipts from this source, against an expenditure of Rs 40,716.

There was a net increase of 40,930 logs over the quantity imported during the previous year, and of 22,847 logs over the importations of 1875-76. In the case of the Salween, the increase is attributed to greater activity in working the Karennee and other forests. It is noticed that the timber of this year is much superior in quality to that imported in the years immediately preceding, and, although the tracts in the more immediate vicinity of the rivers and streams have been well nigh exhausted, there are understood to be still considerable areas of fine forest country further inland, from which however the removal of timber will be attended with difficulty. No reason is assigned for the large increase by the Irrawaddy. It was caused to a great extent, doubtless, by the highly-flooded state of the country, and the consequent unusual facilities for floating timber down. The quantity of teak from British forests entered for duty at Kadoe during the year was again, as might have been looked for, very small, although the floating facilities of the season were unusually favourable. Better results will not be secured until girdling work is again permitted.

Enquiries were made early in the year on behalf of the Admiralty, as to whether a further supply of selected teak timber could be provided, similar to that sent home by the *Dreadnought* in the previous year. In the meantime, however, this vessel's cargo, although selected with much care and trouble, had not on examination quite satisfied the expectations of the dockyard authorities, and further shipments were countermanded. Under present circumstances, it would probably be found impossible to pick out even a small quantity of timber equal to Admiralty requirements.

With the exception of one officer whose ill-health was due in a greater measure, perhaps, to a prolonged and unbroken residence in the country than to any immediate effects of exposure in the forests, the controlling staff throughout both circles escaped serious sickness. As the Additional Conservator points out, the liberal travelling allowances and the youth of so large a proportion of the present staff officers has much to do with this result.

The Planters' Gazette.

TEA.

THE following, from the review in the *Ceylon Times* of the experimental gardens at Peradenya, would not seem to speak well for the chances of tea-planting in Ceylon. "We noticed plants of the China and Assam varieties. The Chinese are eighteen months old, but very stunted; those from Assam are in a better condition, but still hardly in a satisfactory state, considering their age."

TEA-SORTING, FINAL FIRING AND PACKING IN COLOMBO: ITS ADVANTAGES AND DISADVANTAGES.

(*By a former Assam Tea Planter.*)

HAVING read a few days back of the Ceylon Company, Limited, having opened an establishment in Colombo for finally preparing teas for shipment to the English market or elsewhere, I will here make a few remarks on the subject, and point out the advantages and disadvantages of such an establishment. Of course I do not push my opinion as granted, but I have viewed the different sides of the question, and say that such an establishment takes a great deal of responsibility on itself and great credit is due to the Ceylon Company for undertaking to carry out its arrangements.

Before going further into the matter, I must necessarily give a short sketch of how teas are manipulated in order to arrive at the advantages and disadvantages of forwarding teas to such an establishment. In the first instance, as most people are aware, the leaf or flushes are gathered, by women, girls and boys, brought in once or twice a day as the weather stands; on a very hot day I should say twice and on a cool one once would be sufficient: the reason being, not to allow the leaf in the baskets to ferment, as it would on a hot day. When the leaf is gathered, it is taken to a large, cool airy room where it is spread out thinly and allowed through the night to wither. This is one of the most important processes in tea-making, and a great deal of care must be taken that before leaf is rolled it is properly ready to bear the force of rolling; any leaf taken off and rolled immediately will necessarily crack and break up; but by being exposed to air for a certain time will soften and give to pressure; in other words this is called *weathering*, and on this depends the qualities of the teas. When the leaf will give or feel soft on pressure it is ready for what is called a first rolling before it goes through any firing. There are times at which the withering takes longer than at others; during the rains, and when the weather is very cold, the leaf will remain as when picked fresh, and if kept too long before withering will give sour teas (but will not ferment as some people suppose), and to avoid this delay in withering you may pass the leaf over a charcoal fire or through your pan heated to a gentle heat. I have adopted the latter process and found it answer quicker. Here again, when you have to give the leaf an artificial withering, the rolled leaf takes a much longer time to ferment, which is the next thing that it has to undergo, and not less important matter in the manipulation. There is no fixed time to allow for fermenting; your own practical experience must teach you. When you think your leaf is sufficiently and properly fermented the leaf will turn a rich orange or rather copper colour; too deep a tone will give you red leaf, which has more or less to be picked out in sorting; although you may have picked nothing but fine leaf in the gathering, yet it will have to be classified as inferior if over fermented—you either pan your leaf before a second rolling or not, but I most certainly hold to panning to give a fine quality and strength. (You may depend that most of the inferior teas that are sent home and are complained of, were obtained by not panning the fermented leaf; the leaf will not roll so easily.) After this second rolling is over, it gets a third or final rolling, and then it is ready for firing over charcoal fires in what is called a *dhôle* or drum—made of bamboo, or as in Ceylon, cane. It does not do to over-fire your teas the first day, as you are apt to burn your tips or flowery Pekoe away, but give it a gentle firing, and next day give it a stronger one, and put into your bin or large tin or lead lined air-tight box. Your teas are now ready for sieving and sorting for packing—sieves are of different numbers, running from 6 to about 16. For the teas usually prepared on an estate Nos. 10 and upwards are sufficient, as the meshes are close, and teas passing through fine. All remaining in No. 10 may be sorted and packed as Pekoe Souchong; and that which passes through as Pekoe and fine Pekoe or Flowery Pekoe, which does not require sorting. (In a large establishment such as is opened by the Ceylon Company, Limited, a sieving machine, known in Assam as the "Taxidianimeter" patented by Messrs. Parry, Smith & Co., and to be had in Calcutta, is what is required, and will save a very large force of sorters and sievers—purchasing sets of sieves costs almost as much as getting one of these, and there is less trouble than in arranging sieves—one man feeds and another simply turns the handle, when different quality of teas are thrown out on different sides). The teas when sorted and seived are now ready for packing, and before doing so you give your teas a last or final firing, and then put into whatever size boxes you intend, which are previously lead-lined, and packed for shipment.

Having gone hurriedly through the manipulation, the first thing that strikes one is at what stage during the manipulation will the teas bear safe carriage to Colombo from, say, 100 miles, (most of the tea estates in Ceylon are a day's journey from any railway! I think—but am open to correction). We take the first stage after picking: the leaf will not

bear being heavily packed and kept in bulk long, but will ferment or heat, so this is out of the question. The next is during or after fermentation. You would have to do so immediately after the first rolling, and let it ferment during transmission. Here you run the risk of over-fermenting, during any delay which may occur to rail or coolie:—this won't do! Of course it cannot be done after fermentation and before drum firing. After it has received the first or loose firing you may do so; but would have to send your teas in a very air-tight bin or box, as at this or any after stage the teas will sour, and where are you then? The only stage that I can see is just before final firing for shipment home and yet again an air-tight bin would be required, tin or lead lined, screwed down, and opened in Colombo, to be immediately thrown into a bin ready to receive it there; ah! and it runs risks even now. Not that I say every care will not be given to it by the Ceylon Company's manager, and employeés; but where such a delicate thing, as tea is concerned, it requires immediate supervision and attention, and in any delay you risk the value of your teas. In an establishment like a packing and sorting house, you would require, where fifty different estates send down their teas, fifty different bins, and a like establishment of sievers and sorters, as you are apt to get your teas mixed up with those of other estates without there is a very careful and constant supervision in the different departments. It is quite a different affair in China, where the cultivators are more or less ryots and where they sell their teas to the house intending to finally pack it, but not in a single instance do they lose sight of it for final packing, &c., at their own risk by others. In China, a cultivator in a very few instances has not more than four or five acres of tea, and what is made of these few acres is purchased by merchants and others, who then pack or run every risk themselves. I will now go on to the advantages. You have first that of not having a fixed establishment on your estate for soldering, carpentering, sawing, sorting, &c., and you give your tea over to a house that sees that it is shipped carefully away, and not thrown helter skelter into a warehouse or broker's store to be injured in every possible way before shipment.

Taking both sides of the question into careful consideration, I should think the advantages that would be gained by sending your teas down for *more* than mere *final firing, packing and shipping home* are few and far between. I hope I may be wrong, and would *indeed* like to see this enterprising and successful Co. gain wider-spread name than it already has done with the new year, and many happy returns of it by a well-wisher and

TEA PLANTER.

Matale East, 31st Dec. 1878.

We give prominence at this stage in the tea enterprise in Ceylon to the above paper by one whose experience in connection with tea estates and tea factories in Assam qualifies him to speak with some authority. It will be seen that, while very fairly setting forth the advantages and disadvantages of such an establishment as the Ceylon Company, Limited, have founded in Colombo, he rather hopes for than expects unqualified success. In a private note he refers to the failure of a somewhat similar establishment in one of the Indian tea districts, but the circumstances were probably different. Readers interested will form their own opinions, and time will settle the question. We have always had a leaning to the idea of central factories. It is true that tea houses on a modest scale can be erected on estates at a cheap rate; but after a time the difficulty will be in connection with timber for charcoal and boxes. It is of great importance that the boxes in which tea is packed should be as much as possible of uniform weight with reference to questions of tare in the home market, and it is obvious that a firm or company doing business on a large scale would be at an advantage in this respect. Materials for boxes of a suitable timber, well seasoned, could be supplied cheaply in large quantities. So, as regards charcoal, should further experience prove that charcoal heat and charcoal fumes are absolutely necessary for the perfect preparation of tea. The question has been repeatedly raised and those who have read Colonel Money's Prize Essay know that he, in the most iconoclastic spirit, disposes one after another of all the mysteries of tea-roasting by a succession of pans. He finally dispenses with all appliances for firing tea except trays of perforated cloth or metal. Mr. Brace, who contributed an essay to the *Observer*, recommends trays in tiers of not more than three, the under one to be after a time carefully and cautiously shifted to the top. Great care is requisite to prevent any tea leaves falling into the fire and producing smoke. If the muslin netting tea-cloth (Messrs. Walker & Co., have some for sale), or the wire trays, get burnt or heated, damage to the tea leaf will accrue. Even if pans are used, and our correspondent takes their use for granted, there is the possibility of over-roasting, if the pans get over-heated, or are not kept constantly in motion, to facilitate which they are hung loosely. In our own experience, excellent tea has been prepared by such simple means as a cylinder of closely woven matting or of sheet iron, about 3 to 4 feet high, placed over a clear charcoal fire, and the tea leaves, after proper rolling and fermenting, placed over the top of the cylinder, in a tray composed simply of muslin net fixed to a hoop of bamboo. With such simple apparatus excellent and well-dried tea can be prepared, but no doubt ordinary net has the disadvantage of rapidly charring under the influence of the heat which dries the tea. With specially prepared open cloth, with pierced metal, or with wires, there is, of course, slower tendency to destruction, to delay which and to prevent the burning of the tea leaves, untiring care is necessary. There can, indeed, be no question that the preparation of tea requires much more of minute and personal attention than is the case with coffee: the main agent in the one case being fire; in the other water. A division of labour, if it could be successfully effected, is therefore, no doubt, desirable. There is, too, the fact as regards tea, that, instead of a pressure at crop time for a few months, "flushes" of tea will require to be gathered and prepared over a considerable portion of the year. In Northern India the dormant months extend from November to March, but in a country like Ceylon, we suspect there will be little appreciable cession of flushes, except when a chill wind is accompanied by constant drizzling rain so as to counteract the influence of genial sun heat. In the case within our personal experience to which we have been referring, not only are pans dispensed with in the firing process, but there is no sieving or sorting of the tea subsequently. The tea is one kind, a very superior Pekoe Souchong, every single tip as well as every tender leaf being present. In the case of high-grown tea, this surely ought to be enough, and the product ought to command a market, unmixed and on its own merits. To tea drinkers in England it would be cheap at 4*s*. per lb. But the brokers stop the way of any thing so simple. Mr. Burrell would be the man to carry out the idea. Meantime may we ask gentlemen of Indian and local experience if they consider copper pans absolutely necessary for the thorough firing of tea, and, if so, why? Also whether the use of charcoal or other artificial heat cannot be wisely and advantageously economized by the utilization of the sun's rays, in their ordinary condition or concentrated by mirrors? We know that many Indian planters prepare teas largely by spreading the rolled and fermented leaf in the sun, on iron plates or other suitable material. Our correspondent gives an interesting account of the tea-sorting machine. More important still is the rolling machine by which an enormous amount of hand labour is saved, though not entirely dispensed with. Then our good friend Mr. Baker has patented an apparatus for driving excess of moisture out of tea leaves in wet weather—the moisture being expelled by rapid revolution, we believe. Labour is so scarce and difficult in Assam that labour-saving appliances are already largely in use. Here it is only when very large quantities are produced that we need think of machinery. No machine is ever likely to supersede the delicate hands of women and children for the plucking of the flushes. The mode of plucking described in the *Produce Markets' Review*, includes, the taking away of at least a portion of the fourth leaf down from the tip. Surely it would be better for the quality of the tea and for the healthy aftergrowth of the plant, if only the tip, two leaves below it, and half the third leaf, were taken away? What do experts say? On the property in which we are interested, we should never think of allowing four leaves, in addition to those undeveloped in the "tip" to be taken away. Nature must certainly and rapidly resent so heroic an outrage on her laws. But, however gathered and however roasted, clear it is that if tea is to be good and to remain good, it must be jealously excluded from a moist atmosphere. The tea should be put into the bins or chests, hot from firing, and as dry as it can be made without burning. Its subsequent value depends on the care with which it is kept hermetically closed until required for use. Even in an imperfectly made household "caddy" tea will deteriorate. Roasted and ground coffee requires even more care, for the tendency of the charred coffee is to imbibe not only moisture but mephitic gases.—*Ceylon Observer*.

COFFEE.

THE PULNEYS AS A COFFEE DISTRICT.

MR. C. W. W. MARTIN, acting collector of Madura, in a letter to the acting chief secretary to Government from Madura, 11th January, said:—"In reply to your official memorandum, I have the honor to state that 1,987 acres of land appear to have been cultivated during the official year 1877-78 on the Pulneys, and the yield is estimated at 416,892 lbs.

	Acres.	Yield. Lbs.
Pulneys	1,987	416,892
Sirumalais	1,523	448,896
	3,510	865,788

Access is had to the coffee estates on the Pulneys by the Adalur Ghat, and now to a considerable extent by Colonel Law's new Ghat. There are also several hill roads leading from the plains direct to the coffee estates. Coffee planters complain bitterly of the bare-faced way in which they are robbed often by very small children employed by the hill Chetties. The yield on the Sirumalais is 448,896lbs. and the conditions of access are somewhat similar, there being a rideable road from the bottom to the top. Kodaikanal is the station of a second-class magistrate and the bottom of the Adalur Ghat is but nine miles from the joint-magistrate's and taluk station of Dindigul. The top of the Sirumalais can be reached from Dindigul in 3½ hours easily and the return journey is shorter." Mr. Martin having asked that the Coffee-Stealing Act might be extended to the Pulneys, sanction has been given, and the following notification published in the *Fort St. George Gazette*:—"Under the provisions of Section 2 of Act No. VIII. of 1878 ('The Madras Coffee-Stealing Prevention Act'), the Governor in Council is pleased to direct that the said Act shall take effect from and after this date in the Upper and Lower Pulneys and Sirumalais in the District of Madura."

LIBERIAN COFFEE IN TRAVANCORE.

MR. JOHN PAYNE writes to the Madras Agri-Horticultural Society :—"You may recollect the Society about a year ago presenting Messrs. C. B. Dowden &. Co., of Tuticorin, a dozen plants of the Liberian coffee. These they divided among myself and neighbours. Mr. E. Smedly of Arundel two, Mr. T. Miller of Hereford two, Mr. Mathison of Rosemount two, three were planted at Parapet (all in Travancore), and three were kindly given me which I transplanted here (at an elevation of about 2,250 feet) in large pots, 3 feet deep and 2½ wide, covering the same with glass globes, because of the cold and very wet and windy weather at the time ; one shortly afterwards died (it was barely alive when I got it,) the other for six months simply existed, though duly aired and cared for in every respect. Not having in that time grown in the least, I removed them to 'Courtallum,' planting them out in the open, at about at an elevation of 400 feet. Within a week they made a start, and are now doing wonderfully. I should tell you I broke up the pots they came in, and very naturally found a 'network' of roots ; these with a pair of sharp scissors I cut away until there was not a curved bit of root left, or any soil. I mention this, because the other nine plants were planted out by those among whom they were divided, with (in cases) the roots untouched ; in others but slightly pruned (one person planting out pot and all, straw round the pot just as he had received it ! happily the oversight was pointed out to him in time, and one of the two is doing well)—which will account for the throwing out of suckers, to the detriment of the plants and surprise of the growers. Of these nine plants, five are alive and most promising, and with one exception are finer than mine, which I account for by the fact of mine having been kept six months in an ungenial climate. I have no doubt they will in the end be as fine as any. It is allowed, mine for symmetry and being perfect plants carry off the palm. I merely mention this by way of information, and for the benefit of those who may have to transplant plants that have been long confined in a small space, and the roots of which are entangled and altogether out of proportion to that part of the plant above ground. About the same time that the Society gave Messrs. C. B. Dowden & Co., the plants above referred to, it presented twenty to the Scottish India Coffee Company of Travancore. These Mr. James Grant, the manager of the Company, the other day, told me were doing well, and some far exceeded mine in size, but for symmetry, mine were to be preferred, and he had no doubt would soon overtake the others. Mr. Grant expects his to crop next year. The Liberian coffee plants in Madras, so far as the Honorary Secretary can judge, are not doing at all well, though he still hopes to see them improve during this cold weather now commencing, and to be able to write a full report on the subject next year. The plants sent to Travancore were as received from Kew, and were most probably, and so far as the Society is aware, all of one kind, though the habit of two or three of those retained in the gardens differs slightly from that of the majority."

COFFEE LEAF DISEASE.

RESULTS OF EXPERIMENTS CARRIED ON AT WALLAHA ESTATE, LINDULA, JANUARY 1879.

IT has been suggested that, in view of the many experiments that will probably be tried to check leaf disease during the coming season, an outline sketch of the experiments lately carried on at Wallaha and the results obtained therefrom might be of service.

In the following remarks I have tried to summarize what is at present known of *Hemileia vastatrix* and discussed what appear to be the most suitable stages for the application of remedies. I have given special prominence to the effects of sulphur and lime in checking leaf disease from the fact that the two specifics will probably be tried more than any other on a large scale.

In deciding whether sulphur or lime is to be used on a estate at any given time as a remedy for leaf-disease, it is important to note the exact stage of the disease as it shows itself on the coffee trees. If we divide the

LIFE HISTORY OF THE HEMILEIA.

into three periods, under ordinary circumstances, in its *first stage* it consists of fine filamentous threads growing with great rapidity and covering the stem, branches and leaves with a fine network of branching mycelium. This stage lasts for a longer or shorter time (probably from December to March), depending upon the amount of moisture present, and the size of the tree ; the filaments in this stage evidently derive all their nourishment from the moist shaded atmosphere in which they grow, and have no injurious effect upon the tree. But when they reach the leaves they soon begin their work of destruction. The upper side of the leaves being covered by the coating of tough gutta-percha-like substance and having no pores or stomata, the filaments are unable to penetrate it, but on the lower side the leaf does not offer so strong a resistance, and is so full of pores or *stomata* that the filaments find no difficulty whatever—especially in damp weather, when the stomata are wide open—in gaining admission to the intercellular tissue of the leaf. This intercellular tissue occupies the central and lower portion on the leaf and is made up of irregularly placed cells closely packed together, in which, under the influence of sunlight, the food of the plant is elaborated and prepared. These cells, in fact act as a stomach to the plant and carry on a work in the economy of plant life similar to digestion in the animal world. As soon as the filaments of the *Hemileia* reach this intercellular tissue, they tap cell after cell and feed upon their contents. In this way the vital machinery of the coffee tree is destroyed, and it is no matter of surprise that trees affected by leaf-disease suffer a gradual loss of vital energy or that repeated attacks, destroying the young leaves as soon as they appear, at length seriously affect their powers as crop-producers.

The filaments in the first stage, *i. e.*, before they enter the leaves, are so minute, that it is impossible to detect them without the aid of the microscope ; their extreme minuteness may be judged from the fact that it takes nearly 40,000 to make up an inch in diameter.

In the *second stage* the filaments are well established within the tissue of the coffee leaves, and they branch and ramify amongst the intercelluary tissues in all directions. Instead of being long and slender and moderately branched, as they appear on the outside of the leaves, they now assume a thicker, more branched, and a coral-like habit. The terminatives of each branch may be seen in contact and often penetrating the walls of the cells, and gradually the cell contents are absorbed and taken up by the parasite.

The destruction of the intercellular tissues by the filaments may be soon detected even by the naked eye for if the leaves are held up to the light a number of semi-transparent spots dotted here and there over their surface reveal the several points of the attack. As the work of destruction proceeds the leaves become more and more transparent till at last they are almost entirely deprived of their intercellular tissue, and if they do not fall they hang as useless appendages in the economy of plant life.

In the *third and last stage* the disease shews itself unmistakably in the now familiar orange-coloured powder which often covers the whole of the under side of the coffee leaves. The filaments having reached maturity once more push their way through the stomata, and appear on the outside as minute tufts of flexuous threads surmounted by a single sub reniform spore attached obliquely at the base.

Under a moderate magnifying power the spores appears as somewhat kidney-shaped bodies covered on all sides but one with tubercles or wart-like a papilleform point. *As the spores ripen, many of them* fall to the ground or get blown away by the wind, but the greater number remain on the leaves till all the latter are shed.

Judging from the heavy, oily character of the spores, it is probable that most of them remain in the immediate neighbourhood of the tree and except under the influence of strong winds are not distributed over very wide areas. The very rapid spread of the disease may be accounted for by other means than the distribution of these orange-coloured spores, and if what is mentioned in the next paragraph is found to exist to a large extent on coffee trees, it will afford another strong inducement for attempting to check the disease in its first or filamentous stage. After the spores have fallen to the ground or are attached to the stem and branches of the coffee tree, they begin (after a longer or shorter period of rest, to germinate, and the filaments thus produced once more attack the foliage, and the disease once more goes through its several stages as detailed above.

SECONDARY SPORES.

As pointed out by Dr. Thwaites in his report of March 1874, the *Hemileia* under certain conditions reproduces itself by means of *secondary spores* given off by conidia-bearing branches of the filaments. In the report just referred to, Dr. Thwaites, speaking of these secondary spores says :—" At the termination of some of these branches (of the filaments) secondary spores are produced in the form of radiating necklace-shaped strings of little spherical bodies of uniform size, and this form closely resembles the fructification of an *Aspergillus*. Mr. Abbay has also observed another form of secondary spores arranged in single rows of spherical bodies, a good deal larger than those radiately arranged, but still exceedingly minute. These inconceivably numerous secondary spores may be easily carried by the wind into surrounding districts and thus convey infection to distant plantations.

If these secondary spores are produced under normal conditions by the filaments on the coffee trees, they are evidently a source of greater danger as infection-carriers than the orange-coloured spores, and, as pointed out above, they afford an additional argument in favour of

attacking the filaments and destroying them as early in their development as possible.

Many leaves covered by filaments and evidently suffering from leaf disease fall to the ground without producing the orange-coloured spores; this is especially noticeable on old or abandoned estates and on native coffee. It is very probable that under such circumstances (want of sufficient food and poverty of growth) the filaments produce secondary spores in inconceiveable numbers, and if this conjecture is found by subsequent observation to be true, the existence of large areas of abandoned or badly cultivated coffee, (apart from other considerations) is a source of the greatest danger to coffee cultivation in the Island, and must counteract much of the good effected by remedial measures adopted on well-cultivated and highly manured estates.

This danger of infection cannot, however, be used as an argument against adopting any remedial measures on well cultivated estates, for many of them are so far removed from such centres of infection that by the application of remedies they may at least gain one, if not a two years immunity from leaf disease, and the return thus obtained in extra crop would more than compensate for the outlay incidental to the application of lime and sulphur

In the Application of Sulphur

as a specific for leaf disease it is intended, as in the case of the hop mildew, to be a precautionery measure and to act as a check on the disease in its first or filamentous stage, and while it is still an *external* parasite. This is most important, because the disease generally reaches its maximum just before crop time, when the trees can least bear the exhausting effects of *Hemileia* and it is most necessary to check at the outset any development of the *secondary* spores. As the filaments can only be detected in the first stage by the microscope, it is advisable to treat all the trees on an estate, even the healthiest with sulphur. If during the month of February, March, and April advantage be taken of heavy dews to apply sulphur to every part of the coffee trees and on the ground, its value as a specific for leaf disease ought to be apparant during the coming crop time. From the experiments carried on at Wallaba it is evident that when sulphur comes in contact with the filaments and spores it completely destroys their vitality, and if carefully applied cannot fail to lessen the severity of next season's attack.

Flowers of sulphur are preferable to *sulphur vivum* or black sulphur, because it a more certain in its action, and being heavier sticks better to the leaves. If flowers of sulphur can be obtained at Rs. 1[illegible] per ton, it will be much cheaper in the long run than *sulphur vivum* (refuse sulphur) at Rs. 100 per ton. In applying sulphur on a large scale it will require at least 20 sulphur blowers to begin with. If ten coolies are placed to each row—one to use the blower and the other to hold up the leaves so that they can be well powdered underneath—40 coolies thus employed ought to treat 600 trees per hour. On sunny slopes they will not be able to work more than one hour each day, as the dew so soon disappears, but they might be transferred to the nearest shaded slope facing west, where the dew remains, in some cases, it till 9 o'clock. The precarious and uncertain nature of the dew is no doubt a serious hindrance to the application of sulphur on a large scale, but if all the materials for sulphuring are kept ready at hand and a set of coolies—say pruners—are especially reserved for this work and started at day break, much might be done in a few week.

With an abundant supply of dew, the sulphur blowers completely cover the branches and foliage of the trees with a thin uniform coating of sulphur, which remains on the trees for several days, even after heavy rain. Soon after it is applied the sulphur gives off a faint pungent odour distinguished as that of burning brimstone; this is not the smell of sulphur itself but that of *sulphourous anhydride*, SO^2 formed by the combination of sulphur with oxygen. This sulphurous anhydride, or sulphurous acid as it is sometimes called, is a deadly enemy to the fungus, while it is comparatively harmless to the coffee tree.

As in the second stage the filaments are safely lodged within the tissue of the leaves, it is almost impossible to reach them, without at the same time destroying the leaves themselves. This was the difficulty which presented itself to scientific men at home, and from an examination of the dry leaves alone, they were unable to detect the filaments externally, we can easily account for the hesitation with which Dr. Cooke and others recommended the use of sulphur as a remedy for leaf desease. (See report on coffee leaf disease, Indian Museum, 1876, p. 12.)

It the filaments on the outside of the branches and leaves are destroyed on the early part of the year by sulphur, and again if the spores on the newly fallen leaves, and on the ground, are destroyed later on by quick-lime the result must be a diminution of the attack in an aggravated form, and if persevered in, such a gradual amelioration of the disease on well-cultivated estates that its effect would be hardly felt at all.

The application of a prepared

Solution of Lime Sulphur,

which has been recommended by Mr. Abbay, and more recently by Dr. Dias, may have some effect in this stage, if it is practicable to treat a large area with it. A similar preparation has been in use in England for many years as a disinfectant under the name of *Grigson's Mixture*. It is described fully in the *Gardeners Chronicle*, 1854 p. 595.

In experiments with this mixture, which have come under my notice, the solution in the one case was so corrosive that it destroyed all the leaves and in the other was so weak that it was perfectly innocuous. If the solution can be so prepared that it will destroy the filaments of the leaf disease without injury to the coffee tree, the problem will still remain how to apply a liquid of this nature systematically and economically, *of a given uniform strength*, to so large an area as a coffee estate. In any case great care is required in conducting experiments with it, and at first it would be well to operate on comparatively worthless trees. The application of Condy's fluid recommended by Dr. Cooke, lies under many of the disadvantages of the above, but has the one merit of being easily mixed in suitable proportions.

The Fumigating Process,

of which, I believe, Mr. Wall is the consistent advocate, deserves to be carefully tried as a specific in stages one and two. The strong fumes of burning sulphur will undoubtedly kill the filaments and spores of the *Hemileia*, but the process requires to be conducted with caution, in order at the same time not to injure young foliage and flower buds. I regret that I have not had opportunities of seeing the plan tried or of examining filaments and spores under the microscope after they have been subjected to the fumigating process.

Lime, from the difficulty of applying it effectually to all parts of the leaves and smaller branches, and from its uncertain action, especially in dry weather, does not commend itself as a specific for general adoption at this (the first) stage of the disease. From what I saw of its action on Wallaba I would recommend that it be tried as a disinfectant later on, *viz.*:—in the third stage when the trees and ground are strewn with the orange-coloured sporangia.

Application of Coral Lime.

In the experiments with lime, it was observed that the quicklime derived from the ordinary dolomatic limestone of the hills was not strong enough to effectually destroy the spores and filaments, and it would be desirable to experiment in the future with coral lime applied in a dry powdery state as soon as possible after it has left the kiln, and plentifully distribute it over the stem and branches of the trees, and especially over the withered leaves lying on the ground. The most favourable season for the application of lime is just after a severe attack of the disease, when the leaves have nearly all fallen. If quicklime is then applied it will destroy all the spores with which it comes in contact, and by decomposing the withered leaves *in situ* prevent the danger of infection. The plan of

Collecting all the Fallen Leaves,

and burning them, which has been advocated, as a precautionary measure with regard to leaf disease, is a good one if generally applicable to large estates, but I noticed that after a short time very few, if any, of the withered leaves under the coffee retain the spores upon them. The latter soon fall off and are found everywhere on the ground, where sooner or later they germinate and produce filaments which once more attack the tree. It is evident, therefore, that by collecting the withered leaves and burning them, only a small proportion of the spores is destroyed, and taking into consideration the cost of collecting the leaves the damage of a fire on a coffee estate, and the probable scattering of the dry ripe spores which must inevitably take place when the leaves are disturbed, I venture to suggest that it is much better to act on the old proverb, "to let sleeping dogs lie," and destroy leaves, spores, filaments and all with as little disturbance as possible by a plentiful application of quicklime. The value of the lime as a dressing for the soil, and the facility and ease with which it can be applied, are additional points in its favour.

As an alternative process, where it is not possible to apply lime to the whole of the estate at once, the recently fallen leaves, together with a little of the surface soil, might be scraped together, after a severe attack of leaf disease, into one of the number-one *water-holes* found on most estates, and covered over by a small quantity of quicklime. In this way a larger number of spores and diseased leaves might be destroyed at a very trifling cost.

D. MORRIS.

SCIENTIFIC CULTURE OF COFFEE.

THE following is Mr. James Sinclair's contribution to the leaf disease discussion :—

Lindula, 6th December 1878.

Dear Sir,—It has frequently occurred to me, that, in directing our attention *entirely* to the discovery of an antidote for leaf disease, we may be ignoring what is, to my mind, of much more importance, *viz.*, the cause of its appearance on our coffee and a means for preventing it.

Prevention is better than cure!

That specific for this pest will be found in our day, I have no faith in and even if found I doubt the value thereof. That we shall ultimately overcome this great enemy to coffee, I have as little doubt, and that not in the far future. May good luck nevertheless attend the experiments of those who are trying sulphur, porter, &c.

I ask you what would be thought of a community who, in the case of an epidemic caused by bad drainage, bestowed their whole care and attention to curing the sick instead of at once improving their sanitary arrangements.

In my experience of agriculture at home and in coffee planting here, which extends over nearly twenty years, I have proved more than once that any failure of crops by disease is due solely to preventible causes, to a neglect of the laws of good husbandry, not wilfully of course, but through want of knowledge.

At this moment I do not recollect a single instance of a specific being discovered for any of the numerous pests which the farmer

in England is troubled with. Every now and again in the agricultural papers you will read of certain cures, but as a rule, on being submitted to fair trials, they are found wanting. Nevertheless most of the diseases have been either stamped out or are being very successfully combated, but not by an antidote. Even that direst of them all, "potatoe blight" is being gradually conquered and will doubtless in time disappear. Turnip disease, which caused the utmost consternation among farmers on the lighter soils of Aberdeenshire about fourteen years ago, is now so harmless in its effects that you seldom or never hear it spoken of.

So important is this crop to the farmer, that all the agricultural and chemical science possible was brought to bear on it. This, that, and the other cure, such as lime, salt, sulphur, sulphuric acid, &c., were suggested without much, if any, good result.

The farmers gave science up in despair and settled themselves down to watch the effect of different manures, the seasons for applying them, the different methods of cultivating the soil for this plant, till at last it began to dawn upon them that the style of cultivation was bad, and although with ill-treatment they had for a time succeeded in raising good crops, yet the day of reckoning had come, and their whole system must be changed. This has been done and with the very best results.

Now, sir, don't you think that something may be learnt from this? Depend on it, leaf disease is no special visitation of Providence, in the usually accepted sense. "As we have sowed, so are we reaping."

I wish I were as sure that I could point out wherein we have more specially committed a breach of the laws of good husbandry, as I feel certain that we *have brought this on ourselves.* Chiefest amongst them and I make these remarks with due deference to men of longer experience in coffee than I have, is want of judicious and seasonable tillage, a want of method in manuring, &c.

The importance of stirring up soil in England is so well understood that it would be almost superfluous to dilate on it. A striking proof of the advance made in mechanical cultivation during the last few years could be readily understood by a visit to the Paris Exhibition, where implements of all descriptions and prices were to be seen for tilling the soil.

I have beyond a doubt proved to *myself* in Dimbula, how beneficial digging up the soil is, and, in this valley at least, the deeper the better. Soils as a rule, in fact all soils, require aerating or oxidation, now and again, but especially Ceylon soil, where so many of the lower compounds of iron abound, rendering it noxious to vegetation growths.

I have no doubt but that the coffee tree, like many others, exudes or excretes matter deleterious to the soil, which will in course of time render it quite unfit for its growth. I have read of whole forests of vigorous-looking oaks suddenly dying out and in their stead birches springing up and flourishing and in a few years scarcely an oak to be seen. I should think this is a case of the soil being gradually poisoned so to speak, whereas, had it been practicable to expose the soil to the atmosphere, the oaks might still have thriven. What is it but the air and rain water getting into the soil by the edges and interstices of the rocks that makes the coffee bean so well thrive.

But apart from the benefit of exposure to atmospheric influence, by digging a great deal of what must be otherwise wasted would remain in the soil. At the beginning of the year, when crop and pruning have been finished, an enormous quantity of vegetable matter remains on the surface. Now the larger proportion of this useful fertilizer must be carried off by the drenching monsoon rains instead of being taken into the soil, which it would be were it slackened up.

Vegetable matter is most useful as a fertilizer only in containing in the right proportions and in proper condition for absorption by the roots of plants, all that is essential for plant life. Another plea for tillage is that it unsuits the soil for insect or grub life.

In many cases where tillage to a certain extent is carried on—I mean in digging holes for manure, leaf disease, if not caused, is aggravated to a considerable extent so that even in tillage care and judgment must be exercised. A field ought not to be touched with mamotie or hoe for manuring while the soil is quite saturated with water; nothing is so noxious to the soil; of course you can till your soil in a too dry state as well as too wet.

The seasonable tilling of land in England is so well understood now, that should a season chance to be a very wet one while the soil is being turned over, the farmer will tell you that his crops will be attacked by all the diseases they are subject to; every one of them will appear in an aggravated form.

Some very striking instances of this have come under my own observations, but this epistle is already too long.

Liming is a branch of manuring that is much neglected in cultivating coffee.

The same object is frequently attained by an application of quicklime chemically as is secured mechanically by digging. Professor Tanner, of the Royal Agricultural College, in his "Elements of Agriculture" says:—

The advantages arising from the use of caustic lime may be enumerated as follows:—

(1) It encourages the decomposition of the organic matter in the soil.

(2) It neutralises the organic acids which make land sour.

(3) It assists the liberation of the alkaline matters (potash and soda) from the dormant ingredients in the soil.

(4) It promotes the formation of the double silicates.

(5) It favors the production of nitrates of potash.

(6) It contributes food essential for the perfect growth of plants.

(7) It improves the physical character of the soil and promotes healthy growth.

Surely the above is sufficient to convince us of the need we have for a more extensive application of this fertilizer.

Doubtless there are many other ways than that mentioned whereby we *miscultivate* our estates. They will gradually, as we gain experience, have to give a place to a more systematic, more enlightened method of cultivation.

I have no doubt but that the day is close at hand when we shall look back and wonder how the coffee tree lived under the treatment we had been submitting it to.

What is wanted is careful experiment by keen observers—practical men. Frequent association meetings for the purpose of exchanging views and getting fresh ideas. Thus will leaf disease ultimately be stamped out body and soul.

Now a word to those who have seasonably dug, drained, limed and manured, and all in vain; also to those who say they have leaf disease on their unexhausted soil of young clearings.

Disease once generated will attack the well located, well conditioned tree as it will the well conditioned animal, but they suffer less.

Apologizing for occupying so much space, and in hopes that these views may lead to some discussion, from which at least some benefit may be derived.—Faithfully yours,

JAMES SINCLAIR.

AGRICULTURE FOR PLANTERS.

By A. C. Dixon, F.C.S., M.R.A.S.E., B. Sc. & Sci. M, B, (London.)

HAVING pointed out briefly the general geological relations, the physicial properties, and the chemical composition of the soil, as found in Ceylon, and shown that it is of great practical importance to the cultivator to possess some knowledge of its physical and chemical conditions, which reveal the active and dormant powers, and the conditions regulating the transition from a dormant to an active conditon, available for vegetable life, we may now consider its suitability for various crops. The form and elevation of the land, together with the prevailing winds and rain, require to be taken into consideration. Coffee is capable of being produced with profit at various altitudes, from 2,500 feet to 4,500. This may be extended in either direction. Certain kinds, such as Liberian, may even flourish at sea level. Flat districts are generally avoided for ordinary coffee, as the water is apt to accumulate, and *resting in the subsoil does not give the roots full play.* This is much more evident, however, in the case of cinchona, which is near akin to coffee. Food may be eaten by us, but if the stomach juices, such as the gastric, are not there to transform it into such a state as adapts it to the requirements of the body, it will do us no good, nor, if other juices are there, which ought not to be present, will it benefit the body, although all the elements of nutrition may be found. In the same way, the subsoil may endanger the prosperity of the plant.

A careful cultivator will therefore look well to his soil, and can soon find out whether it is too heavy or too light, or, it may be loaded with elements it does not require. If the soil be too stiff and heavy, his mind will naturally suggest lime, or even sand, to keep it open. At the same time, we must bear in mind, that crops may be found which would enjoy a stiff soil.

Again, if too porous, and therefore probably not sufficiently retentive of moisture, he may put clay or heavy soil upon it with advantage. He may keep a heavy soil open, and in a very proper manner too, by bringing leaves, twigs, or other bulky matters into play upon it. The rain-fall in Ceylon, although somewhat out of the ordinary course of things, during the present year, is not too much for coffee. It can stand even more than it has experienced during the last twelve months. If the estates are properly drained, they will not be burdened with moisture—nor if drought should come—and no doubt it will, for even in a climate like this, we cannot get rid of the law, that action and reaction are equal and opposite—it will not suffer much. Soil in a good physical state will draw moisture from the air, and many plants evaporate more water than the rain-fall around them will account for, and this is merely by the wise arrangement that the air always contains more or less moisture. Where we have great heat, we must, as a rule, have great rain-fall, either in the form of actual rain, or dew. As a guide to what a soil is likely to do, it would be advisable to examine the nature of the vegetation already there, and the mode in which it grows. If there is abundance of trees or undergrowth we may take it for granted that the soil has plenty of plant-producing power. The natural vegetation will give us an idea of the depth of the soil, according as it is surface or deep rooted.

We may have plenty of undergrowth, however, of the lower forms of vegetable life, some of which, ferns for instance, do not speak ill of the soil, while others, such as mosses and liverwort, (*Polymorphia marchantia*), great beds of which, I have seen up-country, naturally like boggy places; the soil, or rather peaty matter, is often impregnated to a great extent with iron.

We may have potash, lime, or silica secreting plants, according to the nature of the soil. The weed so common on many estates here—the goat weed, (*Ageratum*)—has similar requirements to coffee, hence this weed is a good index to the soil. It may be troublesome, but it will help to form a very good compost heap. These weeds should not be despised, for if kept in check, they are converting good matter into a better form, and this is not going to be removed from the estate, but returned to it again to form humus. We must not forget that the humus we meet with in the soil is formed of past vegetation ; it is not the cause, but the effect. We may say, in fact, that as iron sharpeneth iron, so cultivation sharpeneth the soil.

The forests, of course, require attention if they are to be profitable to a ~~country, but only a few~~ nations have paid any attention to this branch of agriculture. Perhaps the Germans and French head the list, and it is at the forestry schools of those countries that candidates for that branch of the service must study for some portion of time previous to their being sent out for permanent employment.

A soil over-worked with coffee might be relieved with cinchona, which is not cultivated for fruit, except for the sake of seed, or by tea, which produces a leaf crop. Fruit, leaves, and bark require different matters for their perfection.

The mode of dealing with the rain-fall is a point worthy of consideration. Rain is a most valuable servant, but it must be kept under control. It is too much the custom to treat it as an enemy, which we should clear out as rapidly as possible, instead of controlling it by abstracting the gases, such as carbonic acid, ammonia, and nitric acid, generated by the lightning, in passing through the atmosphere, and regulating the supplies, so as to store them in case of deficiency.

Stagnant water on land is injurious, and in order to prevent this, we must have drainage. Nature has carved out her main drains, and if we wish to get the full effect from the soil around these we must add the capillaries in such a manner as to get the full benefit from the water before it reaches the main branches of the rivers. The mere overflowing of water over tracts of land seldom does much harm, but if it is allowed to become stagnant, it injures the soil considerably, and when it dries up, the sun, acting on the decaying vegetable matter, creates malaria in the neighbourhood.

Dense jungle is almost always moist, for evaporation is checked by the shade of the foliage. The trees, also, condense the vapour in the atmosphere.

The force which removes the rainfall from the soil to the ocean is gravity, or the force of the attraction which the earth exercises on all bodies in a direction perpendicular to the surface of the ocean. The vertical space through which the water moves, is called its fall, and dividing the length of its course by this fall, we get the rate of fall or inclination. When water passes over water, the friction is less than when it passes over the earth, therefore the smaller the surface of earth which the water touches in its course, the smaller the friction. Hence water in a narrow channel will move more rapidly than in a broad and shallow one.

We next come to tillage. We till the ground in order to break it up, and to give the air full play within, as the air helps to digest the food in the soil, and to make it ready for the plant. Tillage is always followed by a good effect, although manuring may not have the same result. Man exerts a great influence on the soil either in the way of improving or impoverishing it. The most fertile soil may become barren by continuous cropping. The term permanent fertility is not applicable in its full sense to any kind of soil, for however rich it may be naturally, its productive power will be diminished from year to year—it may be slowly, but yet surely if no provision is made to restore to it the elements of fertility which have been removed during a long series of years.

I will now give an analysis of an estate soil which I made a short time ago for a gentleman up-country.

Moisture ...	8·4
Organic matter	12·14
Iron oxide	6·38
Alumina ...	8·01
Lime	·23
Magnesia ...	·18
Potash ...	·21
Soda	·07
Phosphoric acid	·17
Sulphuric acid	·1
Silica soluble	2·05
Insoluble silicates	67·05
Traces of chlorine	
Carbonic acid, &c.	

Of the insoluble silicates 17·54 per cent. was quartz, and the nitrogen in organic matter ·19.

I have stated this in the usual form, as much divergence therefrom would probably not be understood; in fact, I am somewhat doubtful whether even this ordinary form is intelligible to many. Some have an idea that the more items the better. For my own part, as far as practical agriculture is concerned I hold that the fewer is the better plan. We only require to know the essential and detrimental elements of plant life. The selection of a sample of soil is important, and I will therefore give the mode of selection recommended to the members of the Royal Agricultural Society of England, by Dr. A. Voelcker, the Consulting Chemist. It is as follows :—

" Have a wooden box made 6 inches long and wide, and from 9 to 12 inches deep, according to the depth of soil and subsoil of the field, mark out in the field a space of about 12 inches square ; dig round in a slanting direction a trench so as to leave undisturbed a block of soil with its subsoil from 9 to 12 inches deep. Trim this block to make it fit into the wooden box ; invert the open box over it ; press down firmly ; then pass a spade under the box and lift it up gently. Turn over the box, nail on the lid, and send to the laboratory. " With coffee soils I would recommend that a deeper portion should be sent.

I will endeavour to explain the foregoing analysis, but in order to make it clear, I must say a something respecting chemical elements. In the elements of our language the letters are divisible in two groups—vowels and consonants. The chemical elements are also divisible into two—the non-metals and the metals. The non-metals of the cultivator are oxygen, hydrogen, nitrogen, carbon, chlorine, sulphur, and silicon. The metals are potassium, sodium, calcium, iron, manganese, and aluminium. Some of these are solids, other gases, some have an affinity the one for the other, and form binary compounds such as carbonic acid gas, a compound of carbon oxygen, and without which plants could not live. A tertiary compound such as sulphuric acid, consists of sulphur, oxygen, and hydrogen. Quaternary compounds, such as quinine, contain carbon, hydrogen, oxygen, and nitrogen. Oxygen, an invisible gas, one of the components of the atmosphere, when it unites with another element, is said to form an oxide. Thus the water we drink is an oxide of hydrogen. The potash we note in the analysis is oxide of the metal potassium, a solid substance. Soda is the oxide of the metal sodium, protoxide of iron is one of the oxides of the metal iron. Alumina, magnesium, and lime are the oxides of the metal aluminum, magnesium and calcium. These oxides are also called bases, since they readily unite with acids to form a salt. For example, hydrochloric acid, better known perhaps as muriatic acid, or spirits of salt, unites with the base soda to form chloride of sodium, or common salt. Sulphate of calcium (gypsum) is a salt formed by the union of sulphuric acid with lime.

An acid is a compound of hydrogen, capable of uniting with a base to form a salt. If the acid contains only one atom of hydrogen it is said to be monobasic, and such acids can only form one class of salts, for example, chloride of potassium, where the hydrogen of the hydrochloric acid has been displaced by the metal potassium. *Sulphuric* acid is dibasic. It contains two atoms of displaceable hydrogen, and can therefore form two classes of salts,—the one normal, where both the atoms of hydrogen are displaced, as in sulphate of soda, or one only may be displaced, forming another sulphate of soda—the acid sulphate so called because it has an acid character. In like manner we have the normal and acid sulphates of potash.

Different elements have different values in exchange among themselves Should the metal displacing the hydrogen have double the value of an hydrogen atom, *e.g.*, calcium, then such element displaces at once the whole of the hydrogen, and we have as a result the normal sulphate of calcium. *Phosphoric* acid is tribasic. It can form three classes of salts —one normal, and two acid. It is on account of this tribasic character that the composition of the salts called phosphates are somewhat difficult to understand.

Now, sulphuric, phosphoric, and silicic acids are mentioned in the analysis, but the reader must not imagine that the soil contains them in the uncombined state in which they are expressed on paper. So long as there are bases in the soil which they like, or scientifically for which they have an affinity, they will unite with them. The sulphuric acid may be there in the form of sulphate of calcium or other base. Phosphoric acid occurring in the soil results from the mineral apatite which is a phosphate of calcium. Without a sufficiency of phosphoric acid we can never get the fruit to mature, so that we need not be surprised to find a tree bring forth sufficient flower, but yet be unable to perfect it.

In order to understand chemical affinity, let a few drops of sulphuric acid be put into a glass of water containing lime in solution ; the acid will immediately lay hold of the lime, forming a white precipitate ; or

should a few drops of the same acid be poured upon a piece of iron, we shall again see the affinity, the acid taking possession of the iron to form sulphate of iron, while the hydrogen is set free.

The insoluble silicates, minus the quartz which is estimated along with them, are silicates of potash and alumina.

Iron, one of the elements in the soil, has given rise to considerable discussion. Vegetation cannot live without it. It is one of the necessary components of that substance called chlorophyll, which imparts the green colour to vegetation, and yet iron, although necessary, if in too great quantity, is injurious. The question naturally arises. How is this? Iron and its kinsman, manganese, the oxides of which tinge our various rocks and soils, exist in two distinct chemical states,—one in which it is fully engaged with other elements, for which it has affinity; and another where it is not so fully occupied. The fully engaged form is the peroxide, the other is the protoxide. This less engaged form is very ready to raise itself to the higher state by taking up oxygen from the air, but this oxygen is required for other purposes, such as to burn up the humus and other matters we chose to put into the soil. These are burnt slowly, without emitting light, just as the oxygen we breathe is used to burn our own food, and furnish us with heat, as well as forming, as a result of burning, carbonic acid gas. If, therefore, the attention of this oxygen is diverted by the presence of the lower oxide of iron, which would be the case to a considerable extent in turning up many subsoils, what else can we expect than injurious effects? The oxygen cannot attend to the iron and its other work simultaneously. As soon as it has satisfied the iron, it will resume its ordinary work.

Some subsoils, when turned up, require frequent working in order to oxidize the iron as quickly as possible. *Sulphur*, one of the components of sulphuric acid, and about which a great deal has been said of late in connection with leaf disease, is very different from sulphuric acid. A planter may read an analysis, and find there sulphuric acid, but this has nothing to do with the leaf disease, nor will sulphur have any effect upon it if placed in the soil, for slow oxidation would then take place, and a resultant compound will be formed called sulphurous *anhydride*, or *sulphurous* acid minus water. All anhydrides are soluble in water, and thus when formed it is not much unlike protoxide of iron in its behaviour. The sulphur in this state is not in full activity; it will readily take up more oxygen, and be converted into sulphuric acid, eventually uniting with some base in the soil, forming a sulphate. If, then, planters think that sulphur put into the soil would be effective, they had better apply sulphate of ammonia at once. Sulphur sprinkled on the leaf while moist, no doubt would be beneficial in its action.

We will now say a little about manures, or those substances we employ for restoring, maintaining, or improving the fertility of a soil. Manures may be divided into three classes: animal, vegetable, and mineral.

The most important is farmyard manure, or in this country cattle dung and urine. The vegetable matter, which has been used in bedding, and earthy matter, which has absorbed the liquid portion, is also of great value.

This may well be called the most valuable manure, since it contains all the mineral ingredients for coffee, and an application of this to each tree would improve the yield, as well as maintain it for two or three years, according to the nature of the soil. Cattle dung is formed from the vegetable matter upon which the animals have been fed, and from which they have assimilated what they required and rejected the rest. It is evident, therefore, that the manure from young animals is not so rich as that from full grown ones, since they require incombustible elements to build up their bones and flesh. The quality also depends on the nature of the food taken, and on the manner in which it is preserved before its being applied to soil. The absorption of the urine voided by the animal greatly increases the value of the solid manure, since it is rich in urea and uric acid, both of which contain nitrogen. The absorption is best accomplished by a free use of earth, straw, or other litter. Straw, being tubular, retains a great quantity, and when it rots adds its own mineral elements to the manure.

Manure may, however, be allowed to become too rotten, and in such a state the gases of decomposition will pass into the atmosphere unless the heaps be protected. On heavy soils, it is well to put it in the ground in a half rotten state, since it helps to keep the soil open. At the best it is but an irregular mixture. One thousand pounds of cattle dung yields about 6 pounds of potash, 10 of ammonia, 3 of phosphate of lime, and 800 of water. The ammonia would result from the decomposition of the nitrogen contained in the dung.

Cattle dung contains all the essential ingredients of the coffee bean, and it is for this that a planter has to apply manure; not for leaves, stem, or pulp, since these are not, or ought not to be, removed. We cannot increase the crop proportionally by adding proportionate quantities of dung. The whole mass in the soil does not come into contact with the root hairs in one year. The continuance of its effect is due to the diffusion which takes place gradually, so that to get an increased effect in a given time, we must apply a much larger mass of manure than that which contains just the required increase of mineral matter in the bean.

But even this is limited by Liebig's well-known law of minimum. "Every soil has a maximum of one or several elements of nutrition, and a minimum of one or several, and it is by the minimum that the crop is governed." We require a certain number of bullock carts to convey from an estate a certain quantity of coffee. If there are more carts than coffee, the coffee is the minimum, and the quantity sent away depends on that minimum of more coffee than carts. The carts are the minimum, and still the quantity transported depends on that. Just in the same way soil must possess, for the production of coffee, potash and phosphoric acid; if potash is in minimum, then phosphoric manures are useless to such soils; or if phosphoric acid is in minimum, then potash manures, if added, are without effect, at least, as far as the production of the crop in question is concerned, unless at the same time we add along with it phosphates to increase that which was in minimum. —*Ceylon Times*.

(To be continued.)

TOBACCO.

It is estimated the out-turn in good tobacco leaf from a properly cultivated acre of land ought not to be less than 800 lbs. In America the average is reported to be usually 1,000 lbs. East Indian tobacco generally sells in London for 1*d*. or 2*d*., and excellent varieties fetch about 5*d*. per lb. The Myouk-toung tobacco is so favorably spoken of that we may with some safety expect the latter price for it. Then if the Government farm there consists of 200 acres (this was its proposed extent.)

$800 \times 200 \times 5 = 800,000d.$, or Rs. 33,333 per acre

or Rs. 2,777-12 per month. Not an unprofitable speculation.

Native calculations, however give 370 lbs. as the average yield of an acre under tobacco cultivation. The calculations then would be

$370 \times 200 \times 5 = 370,000d.$, or Rs. 15,417 per acre

or about Rs. 1,285 per month, even this is not bad. It is probable however, that the native growth would not fetch so much as 5*d*. per lb. But in the Government farm at Ghazipore, and in Bengal farms, 800 lbs. have been readily obtained, and there is no reason why the superior soil and situation of Myouk-toung should not yield as much under proper care and scientific cultivation.

The following is a somewhat important para from the last *Burmah Gazette*:—

Tobacco of excellent quality is produced in Northern Arakan, but its commercial value is to some extent neutralized by the rude and ignorant system which the cultivators adopt in curing it. To educate them in this part of the work, a "farm" was established in the locality in 1877, under the charge of a European who had had large experience in cultivating and curing tobacco. Under his management there was every reason to hope for success; but he started the work much too late in the season, had to contend with very bad weather and a great scarcity of labourers, while, in addition to these drawbacks, he was suffering from a painful ailment from which he soon after died. His successor found matters in confusion, and has confined himself to growing a few acres only of tobacco, on the curing of which he is now engaged. The report on this crop by experts in Calcutta will probably decide the fate of the farm. Should it be continued, the intention is to make it a general nursery-ground,—not for tobacco alone, but for such other economical products as may be considered suitable. The climate is unhealthy,—all but prohibitive either to natives of India or to Europeans even of strong constitution, and, unless the labour question can be solved, there is little to hope for from a district which otherwise has within it the conditions of much possible wealth. The establishment of a steam-launch on the Koladyne river ought to be attended with excellent results.

NOTES ON SOME FOREIGN TOBACCOS AT THE PARIS EXHIBITION.

The following are a few short notes upon the exhibits of foreign tobaccos which were exhibited in the different foreign sections of the Paris Exhibition. Some new facts are also added, collected from the different catalogues, which all more or less contain information of value. The statistical and other information obtained from the different official publications is necessarily much compressed.

Spanish Colonies:—Amongst the different regions which produce the most aromatic tobaccos, alike noted for their *boquet* and their excellence, the island of Cuba is pre-eminently distinguished. The principal Havana manufacturers of cigars have made an excellent exhibition, and there can be no doubt that they have been careful to display only their very best productions. In the Moorish pavilion, where they are laid out, is to be seen, side by side with cigars of the most celebrated brands, leaf tobacco of incomparable flexibility, delicacy colour, and aroma. In fact, the perfection of cigars is to be seen both in the nature of the leaf and the mode of manufacture. In Cuba there are plantations renowned for their tobacco, like there are vine yards in Burgandy and the Bordelais celebrated for their wine; and amongst these the most distinguished in the Champs de Mars are undoubtedly the Lena, the Hotode la Cruz, and Rio Hondo, all in the Vuelta Abajo. The prices of the tobaccos exported from these plantations are very high; they sometimes even reach from 3,000 francs to 4,000 francs the quintal. The well-known brands seem equally to insist,

upon being remunerated for their reputation, and affix high prices to their cigars. We gather from the different Exhibition publications, that the whole of Cuba is not equally favourable to the cultivation of tobacco, but that the planters invariably limit their hopes to the district in which they grow, and are never foolish enough to experiment in obtaining a different species of tobacco to that for which the country is adapted. The richest districts are in the west of the colony. They are the Vuelta Abajo, *Patridos*, and Vuelta Ariba. The first-named is, as is well-known, the most important. Its annual production is about 400,000 bales, of which the average price varies between 20 and 30 piastres for each 100 kilos. of fillings, and from 160 to 200 piastres for the same amount of leaf. Sometimes 100 kilos. of very fine leaf have been known to fetch as much as 350 piastres. The other tobacco-producing districts are the Puerto Principe, Tierra de Adentro, Remedios, Gibara, &c. Here the average price is 12 piastres, the tobacco being of a more ordinary quality. The total production of the Island is now about 42,000,000 kilos., which is nearly one-tenth of the whole consumption of the entire world. In 1852 it was only 20,000,000 kilos. The average value of the harvest is £3,200,000. It is principally in the town of Havana itself that the principal factories are situated. The only protection they receive from the Government is that of their trade marks. These are too well-known to our readers to require recapitulation, but, awaiting the reports of the experts, they seem to occupy at the Exhibition the same positions they occupy in popular estimation. The prices of the cigars exhibited vary between 25 and 400 piastres per thousand. The consumption of indigenous cigars in Cuba alone is estimated at 600,000,000 per annum, and the export to foreign countries is put down at another 700,000,000. The Régie of Manilla and the Planters of Porto Rico have also come forth satisfactorily, but their exhibits poll ridiculously before those of the Pearl of the Antilles. The cheroots are very fine, and will no doubt receive some commendation, but the cigars, though well made, are not very pleasing.

Dutch Colonies.—The tobaccos exhibited in the Dutch section come partly from the mother country (which only produces very coarse tobacco, well adapted for mixing with weak species, of which it corrects the insipidity), partly from the colonies, and especially from Java and Sumatra. The leaf tobacco of Java is remarkable for its beautiful colour, the delicacy of its tissue, and its aroma, which recalls to our mind rather too emphatically the odour of pears. It is admirably adapted for covering cigars. After Cuba and Manilla, the best tobacco for everyday use undoubtedly is now coming from Java. The exports of leaf tobacco from this island are annually worth about £400,000.

Turkey.—The Turkish tobaccos are neither nationally nor worthily represented, and there is little to say respecting their appearance on the Champ de Mars. Some interesting facts are, however, to be obtained respecting them from several tobacco publications at present pervading the Exhibition. The quality of Turkish tobacco, usually very good, is due at once to the climate, to the nature of the soil, and to the particular care which is devoted to their culture, their drying, and their packing by the planters. The Ottoman Empire possesses plantations where, like in Cuba, specially good species are grown. There the price is about 15 per lb.—even sometimes higher for the productions of Yenidje-Karasow, where the best Turkish tobacco is grown,—which is quite as much, if not more, than the finest fancy Cuban leaf, which has been subject to especial attention. Turkey is pre-eminently the land of smoking. It is calculated that about 30,000,000 of Turks consume annually over 100,000,000 lbs. of tobacco, of which nearly the entire amount is used for smoking in pipes. In the Ottoman Empire the indigenous "weed" is subject to a tax entitled "murouryé," without the payment of which no transport is possible. This tax amounts to twelve piastres per oke, which is very large, and contributes considerably towards limiting the exportation. Those species which are particularly in request in foreign countries are the beautiful brown tobaccos of Salonica, Janina, Trebizond, Aleppo, Djebel, and Syria, and those darker and stronger of Mohalieben, Ali, Simer-Kile, Latakia, and Abou-Reha. The tobacco leaf receives in Turkey no other preparation for smoking than being cut very fine and pressed. The aroma for which it is so much liked is due to the species of fermentation which takes place whilst it is being pressed.

SERICULTURE.

TASAR SERICULTURE.

To the Secretary to Government,

General Department.

Jangaon, Ahmednagar, 10th January 1879.

Sir,—I have the honor to submit, for the information of Government the following account of my experiments in tasar sericulture during the past year :—

1. As mentioned in my last report dated 1st May 1877, when I left Poona on famine relief duty, I gave over everything connected with the subject to Mr. Woodrow, the Superintendent of the Government Botanical Gardens, Ganesh Khind, including the cash account of Rs. 871-7-6. In December 1877, I was transferred from the Dharwar to the Poona Revenue Survey, and on my return to the station of Poona in July 1878, for the monsoon recess, I resumed charge of the experiments. The cash balance then amounted to Rs. 421-5-8.

2. My former experiments, as well as those conducted by Mr. Woodrow, had proved that it was a mistake to attempt to rear these worms on twigs either cut from road-side trees, or from those which had received some care and attention in a garden, and that the plan most likely to succeed was to feed them on shrubs in localities where they could be protected from their enemies, and if need be, from unfavourable weather. With this view I began to collect young plants.

3. I had noticed in 1876 that the tasar worm throve well on Lagerstrœmia Indica, an ornamental shrub, fairly abundant in the cantonment of Poona; this is a plant which throws up a good many suckers during the monsoon, and I soon got a few plants together. I took a house which was well supplied with shade and water, and my gardener managed to collect 172 plants between December and July, many of them only a few inches high, but some were large enough to be of use. There were also in the ground 6 bushes, and my first care, when I came in from the districts, was to cut them all back to the hard wood, and apply to their roots a fair amount of manure. The consequence was that as soon as the rain commenced the plants shot most freely into leaf.

4. Mr. Woodrow had not been able to save any seed cocoons, but I had found three female cocoons in the districts, and the Marathi woman, who had been my chief assistant in looking after these worms before, had collected 12. I soon had several moths from these cocoons, and found, as I had noticed before, that there was no difficulty in getting an abundant supply of fertile eggs. Hardly any females were wasted; it was only necessary to put them out over night on any bush, and it was almost a certainty to find them paired at daybreak. I found that it was not necessary to tether them, they rarely moved from the twig on which I placed them. As fast as the young worms hatched out, I put the trays containing them among the leaves of the plants, and in a few hours they commenced feeding. The weather was everything I could desire, showery with a few breaks of fine weather; the bushes were full of young shoots, and the worms throve as I have never seen them thrive before. I tied bamboo screens together and covered over the plants as they stood in the open. The worms changed their skins at intervals of 4—5 days, instead of 5—8, as had been the case when I reared them indoors on gathered food, and they spun their cocoons in 28—35 days, instead of 40—50 as I had noted before. The moths came out of these cocoons in 27—30 days, and their eggs proved fertile, producing caterpillars which grew as fast and as large as the first. The only difference that I observed was that the "cement" of the cocoons of the later crops was less uniformly white; this may have been due to the changes in the weather or the quality of the leaf, some shrubs having been eaten off three and four times this monsoon.

5. The Lagerstrœmia bush proved an excellent food, it flushed so quickly that a plant 2 feet high, after being fed off quite bare, cut back and repotted, was again in thick leaf in a fortnight, and the same batch of worms stript it again. In changing the plants and in daily examining the cages, a few accidents occurred, but 100 worms yielded 71 cocoons.

6. I enclosed an old Carissa carandas, which had neither been pruned nor manured, with bamboo screens and liberated 50 worms there. In the course of a month, I gathered 31 cocoons, a little larger than those of the Lagerstrœmia, but much harder and yellower. The caterpillars seemed to thrive a little better on this bush, and completely stript it, but the tree did not recover quickly and did not yield another supply of food the whole monsoon.

7. I put six worms on to a young Zizyphus jujuba tree in my garden, but neither enclosed it, pruned it, nor manured it. It had a great deal of leaf and flower on it, and the worms ate both. They grew very large and healthy, being in every stage of their existence a little ahead of some of the same batch feeding on Lagerstrœmia. Five cocoons were spun here, larger than any that I had gathered from off the other trees.

8. I let the majority of the moths fly away, for so soon as the male has left her, the female is quite ready to go and look for suitable trees to deposit her eggs on. I had not enough food for more than 100 worms at a time in my own compound, and almost every attempt which I made at bringing them up elsewhere, unsheltered by the screens, failed. Crows, squirrels, and other enemies carried them off, and I hardly got a single cocoon; but in my own compound I continued to rear a few at a time, changing them from one tree to another as I found it expedient. The result of the experiments which I made showed me plainly that plants in the ground with or without screens over them, gave the most suitable food; that it mattered not whether the young shoots were eaten down by the caterpillars or cut off by the pruning shears. The Lagerstrœmia ever sprouted again, and it was only the very limited supply of food, which I had that prevented me rearing many more worms.

9. From the single experiment I have mentioned, Carissa does not seem to recover quickly. Zizyphus seems to grow very fast, principally at the extremities of its long straggling branches, but as I only had one tree in my compound, I could not be sure about its usual habit of growth.

10. I baked some of the cocoons gathered from each of these 3 trees and sent them home to Mr. Wardle, asking him to give me an opinion on the qualities of the respective fibres. I had all the burst and injured cocoons cleaned, and sent them, together with those which Mr. Woodrow had on hand, to the Alliance Mills in Bombay to be converted into yarn. I have kept some fifty seed cocoons for next year's experiments.

11. I have got together a good many plants for next season's experiments—353 Lagerstrœmia Indica; 10 Lagerstrœmia Parviflora; 13 Conocarpus Latifolia; plants and cuttings all rooted and in leaf; also 136 Carissa Carandas, 135 Zizyphus Jujuba, 105 Pentaptera Tomentosa, seedlings; there are besides 3 Zizyphus bushes in the compound; and if my gardener will but take care of these during my eight months' absence from Poona, I hope to resume my experiments under better auspices.

12. The past season has been very favourable for tasar worms. Mr. Lyle, who was cultivating them to a small extent at Dapuri in 1876,

tells me that some of the men who were under him then, came to him lately and asked him whether he wanted any more cocoons as they had seen several. He happened to be on the spot, and sent a man to see how many he could collect within 3 hours. He came back with 300, and said that he had heard that some people had been taking them into Poona for sale, presumably to the native physicians. I myself have already found many more casually this year in the districts than I usually do.

18. During the four months of the monsoon I spent Rs. 136-8-9 in forming the plantations I have enumerated in paragraph 11 and in protecting the worms while feeding. I have still 284-12-6 left out of the money placed at my disposal in 1875, and a detailed account of this expenditure has been submitted as usual to the Accountant-General.

G. COUSSMAKER, *Major*,
Assistant Superintendent, Revenue Survey.

"TUSSORE," IN THE PARIS EXHIBITION.

THE fact that the native silk tissues of India, with their gold and silver mixtures, exhibited in the great Exhibition of 1851, has had a wonderful effect upon the decorated textiles of England is now pretty generally acknowledged by those whose opinions are worth anything upon the subject. The high character of these fabrics, the wonderful texture, the perfect harmony of colour, were a revelation in 1851, and it has been a subject of great interest to inquire how the native weavers with their simple looms could produce such fabrics, and still more how they could with such certainty calculate upon the precision of effect desired being the result of certain combinations of dyed thread when wrought together. Attempts have been made over and over again to emulate, not to say imitate, these effects; but with all the appliances of modern chemistry as applied to silk dyeing, and the great variety of tint produced by these means, even when the original Indian pattern has been taken thread by thread, the European-woven counterpart, although frequently very effective, never had the charm of the original Eastern work, and almost every attempt to produce analogous fabrics in which the pattern was itself European invariably failed in the element of colour. The secret of the dyed silks of India appeared to be impenetrable, but why no one could tell; for, after all, the secret appeared to be on the surface; and so it really is.

The Commissioners for India brought together at the Paris Exhibition a very miscellaneous but very valuable and suggestive series of illustrations of native manufactures of a comparatively low and cheap character, examples of products common among the people of the various provinces of India; and amongst other illustrations was one of the native silk of India—the product of the Tasar, Tusseh, or Tussor worm, or wild silk also examples of the eggs from which moths have been developed during the last summer, and finally cocoons, &c. In addition to the silk itself in its primitive state, examples of thrown silk, "tram" and "organzine," and also dyed examples, there were exhibited specimens of the native dyes from the plants used by the natives for the production of those colours and tints which have been puzzling all Europe for at least the last quarter of a century. In the tints of the dyed skeins, we see the elements of the harmony of the native woven manufactures of India, not produced by costly materials and elaborate processes, but by the vegetable dyes obtained from the common plants of the country and applied by the same simple ingenuity, which reaches its culminating point in the primitive loom of Cashmere. The fabrics shown were chiefly dyed and printed, the printing having been affected in a very suitable and characteristic series of designs by Messrs. Wardle of Leek, to whom the Commissioners confided the experimental illustrations.

The practical issue of all this will, it is hoped, lead to the introduction commercially of these native dye stuffs to the silk and other dyers of Europe. The French silk manufacturers are greatly excited at the prospect of obtaining such dyes, and regard the little exhibit in the India section with unusual interest. It has, however, still to be seen how far the colour and the quality of European silks will come through the process of dyeing with those dye stuffs, and whether the coveted result will be as completely attained as in the soft tints of the wild silk, the product of the same country. Of course opinions differ on this point, but at present they are only foregone conclusions arising out of other conditions of material.

The silk is said to be found "from the north-west range of the Himalaya, south as far as Midnapore, in Bengal and through the north-east range to Assam, and southward to Chittagong, and probably further. It is found also in the residencies of Bombay and Madras. "It is also stated to be abundant in Bhagulpore, in Bengal, and in the eastern district of Chattattisgaib, the Chanda district of the Nagpore province, and the home district. It appears that this special kind of silk has not been much dyed, but the evidence of the examples in the Exhibition proves that it is capable of taking colour in a very special manner as regards harmony to tint, and this fact has to be steadily borne in mind, as it may influence the whole result commercially. The "Tussore" raw silk has a very peculiar natural tint, which may be described as a greyish drab. This may have much to do with the peculiar subdued tint but wonderfully clear colour of the material when dyed, and the whole quality of the chromatic scale as dyed may depend for its harmony upon this peculiarity of the raw silk.

At all events the display of this "Tusseh," or "Tussore," by the India Commission is well deserving of every attention by those interested in the silk trade of Europe, and we have thought it worth while to call special attention to this unpretending, but in its economic aspect, very important illustration of peculiarly native products of our Eastern possessions. The fact that it is grown on so extensive an area, as also that the worm will feed upon a considerable variety of plants are all elements in its future commercial success. As might be expected, the want of fineness and high quality has hitherto been largely owing to an imperfect and unskillful method of manipulation throughout, from the cocoon upwards; and there can be no doubt that with the introduction of proper machinery, and the instruction of native growers, a corresponding improvement will be the result. This improvement is fairly illustrated as regards quality, fineness, and cleanness, in some of the specimens shown, and evidence is given that "Organzine" and "train" of good quality can be produced, and finally woven into a very considerable variety of fabrics in which it has until now been the custom to employ mulberry-grown silks only. There is another interesting and valuable feature of the economic value of this wild silk. The immense improvements made of late years in spinning machinery in England has rendered unwindable and waste silk available for a great variety of purposes, since an even thread is producable from cocoons which formerly were utterly useless. There is, therefore, every prospect that the cocoons of this Tussore silk, which have been rendered unavailable by the premature escape of the moth, can all be utilised and spun for a great variety of purposes.

Specimens of another kind of wild silk—three moths and six cocoons of Attacus Cynthia—were also exhibited. The silk is known in India as Eri, or Eria of Assam. The filament is very delicate, and the natives spin it by hand, like cotton. The yarn is made into a coarse kind of white cloth of loose texture, but great durability; in fact, a lifetime is not sufficient to wear it out. The winding of this Eria silk is stated to have been recently accomplished, but the filament is very fine $\frac{1}{3800}$ of an inch. We cannot but think that a most important future is opening, for the silk districts of India, alike in their wild varieties and in the mulberry-grown silks of Bengal which find their way into the European markets, and by improved machinery have been so largely used of late years. Nor must the fact of the introduction of the native dye stuffs in connection with the native-grown silk be overlooked, although this appertains rather to the artistic side of the manufacture than to its merely commercial aspect.

CINCHONA.

CINCHONA CULTIVATION IN INDIA.

THE introduction of cinchona cultivation into India was undertaken with the object of ensuring a cheap and unfailing supply of the febrifuge for the use of the millions who annually suffer from fever.

Fever is by far the most prolific cause of death in India, carrying off very many more than all other diseases and accidents put together. The total number of deaths from fever in India is upwards of a million and a half annually. At least half these deaths will eventually be prevented by putting some cheap form of the cinchona alkaloids into every druggist's shop in the country at one rupee per ounce; and thus multitudes will be saved from death or grievous suffering.

The successful introduction of cinchona cultivation into India has been a task of considerable difficulty in all its stages. It was not only necessary to transplant a genus of plants from one side of the world to the other, it was also an essential element of success to convert wild into cultivated plants. This involved a close study of the climate, soil, and general physical aspects of each region where the valuable species grow in their native forests; a comparison of these circumstances with those prevailing in the East Indies, the discovery of the best species, and also of the species best adapted to secure good results in their new homes, the study of all the requirements of the plants under cultivation, without any guide, as the cinchona had never before been cultivated; and finally, the solution of numerous very complicated questions relating to the best and cheapest form in which the febrifuge can be provided for general use.

The task was difficult and complicated. Mr. Markham undertook it in 1852, and all arrangements connected with the collection of plants and seeds in South America, and their conveyance to India, have been made by him, and carried out under his superintendence. His original plan was to depute collectors to the different regions of the Andes where the various species flourish, to have the collections made simultaneously, and to convey them direct across the Pacific to India in a special steamer. But only a portion of his

scheme obtained sanction, and no steamer was provided. He was, however, determined that all the species should be secured eventually, and that the work should be complete, even if it extended over many years. This has been the case. It has taken many years to do what might have been done in one or two, and the expense has been quadrupled. Yet the whole work is now at last complete.

In 1859 Mr. Markham was only able to organise three expeditions; one under his own command, to obtain plants and seeds of the calisayas and other species from Caravaya in Southern Peru, yielding the yellow barks of commerce; a second, under Mr. Pritchett, to collect species in the forests of Central Peru yielding the grey barks of commerce; and a third, under that eminent botanist Richard Spruce, to collect plants and seeds of the *cinchona succirubra* in the forests of Ecuador, yielding the red bark.

In 1860 the whole of this work was done and done thoroughly, so far as the difficult and dangerous part of it in the Andean forests and the conveyance of the plants to sea ports on the coast of the Pacific, were concerned; but the failure to furnish the means of direct conveyance to India led to disasters which were inevitable. The plants had to be conveyed across the Isthmus of Panama, then to England, then cross Egypt, and down the Red Sea to India. The first instalment from Southern Peru all died on the passage, or after reaching India; but the seeds forwarded in the following year germinated, and thus a stock of *C. Calisaya* trees was secured. Subsequently more seeds from Bolivia, collected by Mr. Ledger were received, and the plants raised from them have proved to be an exceedingly valuable variety, which has received the name *Ledgeriana*. The second instalment of plants consisting of those yielding grey bark, was equally unfortunate, but the precaution had also been taken of obtaining seeds from which a stock of plants yielding grey barks was established in India. The third instalment, coming at a cooler season for passing down the Red Sea, was more fortunate. It consisted of plants of *C. succirubra*, yielding red bark, nearly all of which arrived safely. Thus by 1862 the arrangements made by Mr. Markham as regards the above species were crowned with complete success; but the work of introducing all the best species was still far from finshed. It remained to obtain the valuable species from Ecuador, yielding the crown barks, and also the renowned species of Columbia.

Accordingly Mr. Markham obtained sanction for the despatch of a collector to Cuenca and Loxa in southern Ecuador to obtain seeds of the *C. officinalis*, the orginal species of Linnæus (afterwards called *C. condaminea*,) from the bark of which the Countess of Cinchon was cured. For this service he selected Mr. Robert Cross, an experienced gradener, who had already acquired experience under Mr. Spruce, with instructions to obtain a supply of seeds of the best Loxa species yielding crown bark. Mr. Cross reached Ecuador in 1862, made a good collection in spite of extraordinary difficulties, and the seeds arrived safely in India and Ceylon, and germinated freely. Mr. Howard, the well-known quinine manufacturer, also presented a fine plant of *C. officinalis* (von *Uritusinga*) from which a large stock has been obtained. Thus the introduction of the crown bark species was secured.

Mr. Markham's next care was to obtain and introduce plants of a valuable species called *C. pitayensis*, which grows on the slopes of the Central Cordillera of Columbia, near Popayan. For this working he again secured the services of Mr. Cross, who set out in 1863 and made a good collection of seed, but, owing to damage suffered in their transit, they did not germiniate. After some delay Mr. Markham obtained sanction for a second attempt, and in 1868 Mr. Cross again set out for Columbia, this time with more fortunate results, for seeds of *C. pitayensis* collected by him near Popayan arrived safely, and germinated freely in India.

Meanwhile the destruction of *C. pitayensis* in its native forests led the collectors to seek for other trees in more distant regions, and a new bark began to appear in the market, of great value, known as the *Calisayade Santa Fé*. Mr. Markham resolved that this species should also be introduced into India. The service was one of special difficulty and danger, for the trees are only found on the eastern Cordillera of Columbia, near the sources of the Cagheta. He again intrusted the work to Mr. Cross in 1877, and again his confidence in that intrepid and most able explorer was justified. In March 1878 Mr. Cross arrived at Kew with a good supply of plants of the *Calisaya de Santa Fé* and also of the *C. cordifolia*, yielding the Carthagena barks of commerce.

Thus at length all the valuable species of febrifuge cinchona plants, indigenous to South America, have been successfully introduced into India. They are as follows: -

C. Calisaya (yellow barks) Bolivia and Caravaya.
C. nitida, *C. micrantha*, *C. Peruviana* } (grey barks) Central Peru,
C. succirubra (red barks) Ecuador.
C. officinalis (crown barks) Ecuador.
C. Pitayensis } (Pitayo bark) } Columbia.
Calisaya de Santa Fé, *C. cordifolia* } (Carthagena barks) } Columbia.

The first and most hazardous stage of the enterprise was the collection of the plants and seeds in South America, and their conveyance to India. The second equally difficult stage was the cultivation and the discovery of the species best suited for India, as well as the best method of treatment with a view to producing the largest percentage of febrifuge alkaloids in the barks.

The first step was the selection of the most suitable sites for the plantation, being those having most resemblance to the native habitat of the cinchona. Mr. Markham proceeded to India in 1860 to perform this duty; and chose a site at Neddivuttum, on the northern slopes of the Neilgherry Hills, facing Wynaad for the plants of *C. succirubra*, the *C. calisaya* and grey barks; and a site at a greater elevation, under the Dodabetta peak, for the *C. officinalis* plants. He also selected sites for plantations in Coorg, and the Pulney Hills, and on the occasion of a second visit. to India in 1866, in Travancore and Wynaad.

The successful conversion of the cinchona from a wild to a cultivated tree is due to the unrivalled skill and ability of the late Mr. McIvor, superintendent of cinchona cultivation, in the Madras Presidency. Mr. McIvor propagated the plants with great success, established them in the plantations, discovered the conditions under which they would give the largest yield, and also the method of renewing the bark by the mossing process, which undoubtedly secures an increased percentage of febrifuge alkaloids. The final conclusions are that the *C. succirubra* species is best adapted for use in India, and for furnishing abundant supplies of a cheap febrifuge while the *C. officinalis* and the Columbian kinds will be the most valuable barks for the London market, and for the securing a remunerative return on the outlay. By 1870 the Neilgherry cinchona plantations, belonging to the Government covered 1,200 acres of ground, while private individuals possessed several thriving and paying plantations on the Neilgherries and in Wynaad, 235,747 plants having been distributed up to 1875. In the same year there were over a million cinchona trees in the Government plantations.

In 1862 a cinchona plantation was established in British Sikkim, under the superintendence of Dr. Anderson; plants, of *C. succirubra* having been obtained from the Neilgherry hills. Other kinds are not likely to flourish in the Sikkim climate, but the *C. succirubra* is well established in the Rungbee plantation. By the year 1875 there were upwards of two million plants of *C. succirubra* at Rungbee, and the propagation can be carried on with ease to any extent.

Thus the second stage of the enterprise, namely the cultivation, was crowned with complete success.

The third and most important measure is the supply of a cheap febrifuge to the people. As soon as it was established that the *C. succirubra* would be the best species for India a very critical point arose. That species yields a very large percentage of total febrifuge alkaloids, but only a small quantity of quinine. Mr. Markham saw that it was of vital consequence to discover the medicinal value of the other alkaloids, namely cinchonidine, quinidine, and cinchonine; and to ascertain whether they, equally with quinine, possessed the precious febrifuge qualities. He accordingly obtained the appointment of Medical Commissions in 1866 for each of the three Presidencies, to investigate and report upon this question. The result was that cinchonidine (the principal alkaloid in *C. succirubra*) and quinidine were found to be quite equal to quinine, and cinchonine inferior, though still efficacious in larger doses. This was a great point, for it made a cheap febrifuge medicine possible. The extraction of pure quinine is an expensive process, but the production of a medicine containing the total alkaloids in the bark is easy and simple.

This important fact having been established, Mr. Markham next urged the adoption of cinchona cultivation into India; namely, the preparation of a febrifuge medicine at the Government plantation, which should contain all the alkaloids, and should be saleable at a cheap rate. With this object Mr. Broughton was appointed as quinologist on the Neilgherry Hills in 1866; and in 1873 Mr. Wood received a similar appointment for the Sikkim plantations. Mr. Broughton adopted a method for the manufacture of his medicine which entailed the use of alcohol and was, therefore, too expensive. Up to 1873 he had made about 600 lbs. of an amorphous cinchona alkaloid, but the essential requisite of cheapness was not secured. His method was consequently abandoned. Mr. Wood began his actual manufacturing operations in 1875. His method is the same as that recommended by the learned quinologist of the Hague, Dr. J. E. De Vrij, who calls the resulting product *quinetum*. The powdered bark is first exhausted with cold acidulated water, and the resulting liquor is precipitated by a caustic alkali. Scarcely any fuel is required and no expensive machinery merely some wooden tubs and calico filters. There can soon be yielded, by his process, about 140,000 ounces of an efficient cinchona alkaloid every year at a cost of less than one rupee per ounce. Quinine, in England is from eight to nine shillings an ounce, and in India the price is much higher.

Thus the great object of this difficult undertaking is on the eve of being secured; and an inestimable blessing will be conferred upon India; while at the same time the barks rich in quinine will be sold in the London Market, and will repay all the outlay with interest. The sum of £40,000 was realised by these sales in 1877 alone. While on the one hand, cinchona cultivation will be a most remunerate public work, on the other it will rob the malarious fevers of India of three-fourths of their victims, and will to that extent diminish the amount of human misery and suffering.

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah *in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.*

WILL F. L. kindly send his address to the Editor who has a communication to forward to him.

LETTERS TO THE EDITOR.

ARTESIAN WELLS.

SIR,—May I request you, or any of the readers of your valuable journal to be kind enough to give the public some information regarding Artesian wells, which have, I hear, been constructed in Pondicherry, Madras Presidency; such as the cost of their construction, and the feasibility of constructing them in the Madura district.

INQUIRER.

Dindigul, 1st March 1879.

INFORMATION WANTED.

SIR,—Will you kindly permit me to put the following questions, the solution of which would put me and my country under your highest obligation.

1. What are the best means, natural as well as artificial, to obtain a large quantity of gum and lac from such trees as are capable of producing them.

2. Which trees or rather which kinds of trees can be best propagated by cuttings, and which by seeds?

3. Would you recommend liming a soil extremely sandy? Certainly not.—ED. *I. A.*

INDIAN AND AUSTRALIAN WHEAT.

SIR,—I have had special opportunities of seeing various cereal grains lately. I find that the wheats exported from India are full of filth from the mode of threshing. They are also mixed with vetches and barley. In striking contrast to the Indian wheats, I find that the wheat from South Australia is perfectly clean. It is cut there by a machine called "Ridley's reaping machine." This implement will work only when the wheat is well ripened and dry; but those conditions are generally met in the N.-W. P., at any rate after the sun has caused the dew to evaporate. The machine simply cuts off the ears and extracts the grain from them as it travels along. I am convinced that if it can be adapted to bullock labour, the introduction of this machine would prove a great boon to upper India and Scinde. It would get in the corn free from the dirt of the "kunnun," and would moreover leave the low growing pulses untouched. Of course if the villager sows "goojai," the machine would turn out goojai. I merely give you the hint for what it is worth, but I hope that some enterprising zemindar or official will prosecute enquiries from the Government of South Australia. If Indian wheats were reaped like Australian wheats, they would bring a far higher price than they do in the English market. The machine I write about is made in Australia, and I have not as yet been able to discover a single specimen in England; but if any of your readers interest themselves in the subject, I shall be very happy to assist them in making further enquiries.

H. MIDDLETON ROGERS, LATE B. C. S.

20, Corn Exchange Buildings, London.

DETERIORATION OF TEA SOILS.

SIR,—In the *Indian Agriculturist* for February 1st, 1879, there is a very clever and interesting report of Mr. E. C. Schrottky, on the subject of Kans Grass in the Banda district, in which he states :—

"If Kans has taken possession of any field and is left alone, it "exhausts itself after ten to fifteen years' continuous growth (or rather "exhausts in that period the peculiar elements in the soil which support it). If, however, the soil is disturbed or cultivated, Kans will

"last longer (that is to say, when atmospheric and climatic influences "are allowed to act more freely upon the soil, by stirring it up, there "will be set free from chemical combinations some more of the peculiar "elements, Kans is partial to and the additional nourishment thus "furnished, will prolong the existence of Kans beyond the usual period)."

The above exactly represents the present state of the case as regards tea cultivation—"the peculiar elements in the soil which support the tea-plant are being exhausted" from over-plucking; and although manuring is largely carried out on many gardens the exhaustion above alluded to is but delayed, not prevented; which can only be neutralised by giving the plants a rest, and allowing them to mature their "flush" leaves, say, once in four years, letting the natural vegetation of the place grow in its own natural luxuriance, mature its seeds, and die down, after which dig it all in and carry on the cultivation in the ordinary manner.

It may be said that shareholders will object to losing their dividends every fourth year—better this, though than not obtaining any for half a generation, or perhaps for ever. Still matters need not go this length, but may be avoided by plucking annually fr m only three-fourths of a plantation leaving the other fourth fallow and thus give the plants rest onc f r years, and allow them to [illegible] and r [illegible] their seed and to be in [illegible]atural a state as it is pos[illegible] le for a cul tivated economic plant to be.

The present system of continuous plucking of th new le [illegible] resembles the operation of killing the goose that laid the golden eggs Assist Nature and she will reward you, try to force her and punishme t will surely ensue.

G. P. P.

KANS GRASS.

I.

SIR,—I was much interested in reading Mr. Schrottky's on Kans Grass, in the *Indian Agriculturist* for February 1st. Having been at Jhansi in 1874, where we had relief, works, in consequence of the distress it produced, I came across a good deal of kans and was very much struck with the phenomena which attend its appearance. My attention has been a good deal drawn to Agricultural Physics since leaving Jhansi, and after thinking out [illegible] matter, I felt s[illegible] sfied that the appearance of Kans signalized the exhaustion of the soil in a manner about which there could be no mistake. I observe Mr. S. states "that injudicious exhaustion of the soil is one of the causes of its appearance." In fact the then Commissioner of the district told me at the time, and a native cultivator complaining to me of kans also admitted the fact that [illegible] the people tilled and manured their land, they got the Kans down, but I am afraid, it will be no easy matter to get such a measure as this enforced as a matter of public safety. Having occasion to look through a set of analyses of Indian soils abo[illegible] two years ago, I came across one of a soil in the native State of Tehree which joins on to Jhansi, and is close on th[illegible] Kans devastated tract, but not so far as I have seen, as yet affected. Comparing this with the other soils, I was struck with the small amount of sulphuric acid present and pointed this out to Mr. Harman of the Mysore Agricultural Department, who considered the matter worth noting. I remark the same thing in Mr. Schrottky's analysis of Banda soil. Potash, soda, chlorine and sulphuric acid, together, only amount to 0.56 in No. II overrun field, wh[illegible] in No. I they are 1.28. So that the sulphuric acid must be a mere trace. Now it is curious that in Mr. S.'s analysis of Kans ashes there is only 0.8 per cent. in the plant. Turning to the tables in Mr. Schrottky's *Principles of Rational Agriculture* I notice that most of the useful plants require a very much larger proportions than this annual rye grass for instance, as much as 3.45 per cent., wheat straw 3.6[illegible] rye straw is the sole competitor with Kans for the short commons of 0.8 per cent. Indeed I once made a formal allusion to the Jhansi famine caused by Kans and with some diffidence suggested that an analysis I had seen, indicated the absence of enough sulphuric acid as the promoting cause of Kans. I also stated broadly my impression that the grass betokened that the land was exhausted, and t at as far as I had seen there was nothing to prevent its appearance o[illegible] the entire adjoining districts in time. I see in Johnson's *How Crops Grow*, an American book, that in the oat plant SO_3 exists much more in the leaves than in the stem, and that on blossoming apparently the sulphuric acid deserts the lower joints of the oat stem entirely. Now my recollection of Kans is, that it has the appearance of animated straw when growing, there being little green leaf about it, so that it is by constitution a plant, which might be expected to contain the minimum of sulphuric acid.

P.S.—Lime as sulphate.

In Tehree soil	... ...	0.602 per cent.
„ Lower Bengal soil	... ...	0.414 „

No other sulphates in the analyses.

A. T. F.

II.

SIR,—Having read Mr. Schrottky's report on the weed called *Kans* in the local *Gazette*, I take the liberty to express my own theory and thoughts on the subject. They are based solely on practical knowledge of the soil. I am a land holder of a few villages in the district. Mr. Schrottky's remarks on the causes of its growth are learned, mine are vulgar and purely rural. If you consider these few lines worth anything, you may kindly insert them in some corner of your valuable paper.

Kans is a weed which grows particularly in *mar* and *caber* lands, and seldom in rich *pundwa*; but is almost unknown in *ranker*. The former two are considered the rich[illegible] soils for cultivation and the latter are light ones.

Irrigation and manuring are almost unknown in the district. Farmers solely depend on rain and air. They do not plough deep, nor more th[illegible] once, but [illegible] w the seeds in big clods. When they have extracted from the soil, element[illegible] pe[illegible]liar for the growth of certain crops without changi[illegible] [illegible]en.. and the d[illegible]ficiency is not supplied by any artificial mea[illegible] [illegible] mes impoverished, and must needs have recourse to some natura[illegible] [illegible]nod. [illegible]hen the land is exhausted or when those fructi[illegible]ng elements are washed away by heavy rains, this weed must grow up. [illegible] reason why this weed has such long roots, I think, is because the soil was full of those elements, but when they have become extinct on the surface, they still exist under it at a certain depth. It is a natural means to pump up those elements to the surface of the soil by capillary process, and when it has performed its functions it dies a natural death.

This is a very slow process, but at the same time a most certain one, which very often takes seven years to perform. Now it is the business of an experienced agriculturist and practical chemist, to invent and introduce a more steady method. It must at the same time be a cheap one, otherwise it will be of no use, more especially in this poor district. I know nothing of phosphoric or any other acids, because I have no means to analyse the soil, nor have I a sufficient knowledge of chemistry. I may venture to state a vulgar method which may suit the means of the poorest class of farmers not quite unknown to the people at large of Banda district. If the cattle are kept feeding on the fields, the *kans* will not grow, and if the soil is already infested with the weed, it will vanish sooner

There is another method which I mean to try next season—and which if proved successful may still be a more expedient method. I mean to make ditches around the field and to have a sort of embankment round them, in order to pr[illegible]vent the water f[illegible]m running away. This must be in addition to the above process

These are my own thoughts, I have never had an opportunity of reading those treatises named in Mr. Schrottky's report.

A FARMER.

Band[illegible] [illegible] 1879.

N[illegible] [illegible] tion to the above experiments, why does "a farmer" not *sow* a portion of the Kans infested land, as recommended by Mr. Schrottky. —ED. *I. A.*

BAMBOO.

SIR,—I find that in my last letter to you of the 23rd January, I omitted to call your attention to the last report I received from Mr. Robert Thomson, page 27 of the brochure I sent you at that date.

The letter you published from me in your January number, gave the matter of my communication to the Secretary of State for India, therefore I assume you would not repeat that portion of my print.

I now send you copy of extract from the Demerara *Royal Gazette*, January 9th, which perhaps you will see well to insert, as it bears on the point of growth, produ[illegible]ion, and cropping of the bamboo, and *cæteris paribus*, there should be no reason why what dame Nature effects in the West Indies should not likewise be obtainable in the East Indies.

Extract from the *Royal Gazette*, Demerara, West Indies, January 9th, 1879.

Regarding the local [illegible] of bamboo so strongly advocated in his letter to Mr. William Walker (which we publish) one of our country readers writes thus —"Demerara is not specially suited for "bamboo unless the plant has good drainage and plenty of room. In "the [illegible]ward Islands where it has both, it grows to a gigantic size; "but here it is a poor [illegible]ing. The low lands abutting on the sea are "not good for it, as they are salt, and undrained; bamboo blossoms "even when it has been cut for firewood the year before, I have seen "it several times, the stools did not die, probably because the stalks "were not too old, and were succulent and healthy. At an estate I was "on, we had large quantities, and every [illegible] were cut clean of, "and close to the roots, and the next [illegible] had *the same supply*,

"say 1,000 cords of fire-wood. Every body knows that the way to "plant bamboo is by the cutting. If the soft stalks only are required "for paper, *two cuttings a year* could easily be got ; in 12 months the "stalks are hard and good for fire-wood or for making sub-soil drains ; "the young shoots say 6 or 9 inches long (as they come out from the "stool, after a cutting especially) make a delicious pickle made ... like "walnut, or cabbage, or paw-paw, &c. Why cannot the R. A. and C. "Society give a prize for an *essay written from an actual knowledge of "facts*? It is a fallacy to suppose that bamboo is going to grow either in "a swamp, or a hard, dry, and perhaps salt pasture on the front lands. "It *must be* well drained, kept clear of bush, and have water, not "stagnant water, but good rain or running water," My correspondent in Demerara (an estate-holder who sent me the above extract adds "I have seen on this estate clumps of bamboo ... and ... "remained quite health, afte..rds, I have cut them down flat to the "roots, and also burned them, but in a few months they were as "flourishing as ever."

The above assuredly does not coincide with Dr ...'s experiments ... *possibly*, the variety of bamboo may have ... the reason, or the age of the clump, as an aged ... of bamboo, like an old man may lose its vigour of ... Dr ...'s experiments were conducted on clumps of *Bambusa* ... the variety of bamboo indigenous to Demerara I believe to be *Bambusa* ... probably however the reason may have been climatic influence, insufficient moisture, at any rate cutting down the whole of the shoots both old and young should I think be avoided.

THOS. ROUTLEDGE

Claxheugh, Sunderland, 20th Feb. 1879.

BEE-CULTURE.

SIR,—Your valuable paper has often ... inted with reference to bees, and the advancement of bee culture. I write the following as regards the wild honey-bee of the sub-mountain tracts that have come under my observation.

There are but two descriptions of wild honey-bee in these parts, but natives of Oudh tell me, there are four in their country.

1.—Punjabi *Bhardo*, Oudh, *Sar...ng*, a honey-bee exceeding half an inch in length, head and thorax black with greyish yellow hairs at its base, the whole form elegantly symmetrical, the abdomen orange-yellow longish, the white and black bands or segments not distinct, the extreme segment forming stinging apparatus blackish wings metallic and blackish. They are very fierce, and if disturbed will swarm out and put all to flight w... a considerable ... they ... settle down again. I have ... will ... to the extremity ... was once to ... still, attacked ... to breathe, they left ... a stout branch of a ... never broad, so that the ... from ... They a... under the eaves of houses and ... so that they are ... of domestication, for it is said the ... will species No. 1, ... the hollow of trees. If not irritated they are harmless, and the ... be obtained by smoking, generally at night. The ... yellowish, and the wax ... England, in the Stabau bee ... honey ...

No. 2, Punjabi *Chota makhi*, Oudh *S...*, This is a small ... not even half the size of the last, it is ... colour, the white and black bands, four or five, very distinct at lower part of abdomen, wings ... parent, very light grey. It is a very harmless creature and not ... Their honey is very fine and white crystallizes in winter. The hive is not very large. The habits the same as above. ... geological pastime in the salt range, a native ... a few steps off the road having ... Both these varieties are very plentiful ... since fruit and forest trees abound, ... requires food for them to ... hills the Chachura, the white ... to draw them.

No. 3. Punjabi *Dhamala*, Oudh ... No. 2, the hive largish. Honey ... domestic bee of the Kangra and Chumba h... to ... bee hives formed in the shape of a drum with a ... as would be the better description, they place ... and have the holes outwards, generally ... with ... when they extract the honey from the ... smoke them out; they transfer them at the swarming season by smearing some sweets in a new hive ; the people only feed them in the winter when the snow interferes with the bees resorting to wild flowers ; the food is then a parched grain (*seinul*?) with gur. The plentiful wild flowers, especially the Labiatae, are sufficient to feed them.

No. 4. No Punjab name, Oude *Bhusami*, this is a trifle smaller than No. 2, and may be the true representative of the wild bee, for it builds in the hollow of trees. It is darkish of colour. The honey is somewhat tart.

A French *savant* in a monograph on bees, states that bees were originally brought to Europe by the Arayan races, for they were not indigenous. Bees and honey form a portion of the offerings at the "Hum" sacrifice. I find in the Vedas, and even now are used at "shraddas," but as to their having been carried to Europe by the Arayans is an open question. Perhaps it is so, as the cereals were also taken by these people when migrating. But bees are wild in the hills of India, and my getting ... in the salt range, brought to my mind the times of John the ... It is probable that bees, cereals, &c., formed a portion of the ... old, belongings of the Caucasian races and were carried by them ... they ... settled in.

It is well known that bees were unknown in North America ; the Red Indians ... "English fly." There is no ... here also, and need not be confined to the ...

W. W. BUCHANAN.

Guzerat ... March ...

HILL FARMING.

(*Extract ... Madras Mail*)

SIR,—In estimating the capabilities of ... district for meat producing, its suitability for the growth of turnips ... highly important matter. Turnip growing, and the use of bones as manure quite revolutionised the farming system of England, and according to competent authorities, about trebled the meat-producing capabilities of the country. A Yorkshire Farmer writes, "Bones form one of the most valuable manures for turnips on all light soils, on account of their portable and stimulating character, they have converted barren moor lands into rich fertile, and productive farms, luxuriating in every valuable product of the country, their value is beyond all praise." Another writer, says, "All comparatively dry soils, from the poorest sand and gravel, up to the richest free loams, are more or less suitable for turnips."

These two short extracts show us exactly what could be done to bring the Hills into a condition for producing meat. We have exactly the soil required, not in patches as it is found in England, but the whole cultivatable area of the Hills is what in England would be classed as "turnip soils." The apparent difficulty is its poverty, but the grass lands of the Hills are not naturally poor, they have been ... by being grazed over for generations, and receiving nothing in return, not even the droppings of cattle, for that is washed away by the first heavy rains but it was found on the farm that the grass ... was equal, if not superior to sholah land. All that was required was a heavy dressing of manure to bring it into condition. The difficulty to be faced was the getting manure to start with, but with bones as a manure the difficulty can be got over. The great advantage in using them is their portability ; sixteen bushels is ... calculated to be sufficient for an acre against thirty cart loads of farm yard manure, and once having brought the land into condition and stocked it, the up-keep becomes easy.

Now, let us draw a comparison between the Hills and England as turnip growing countries. In England there is about a month and a half during which turnips can be sown. Only one crop a year can be raised, and these have to be raised, and stored during the winter at considerable expense, and heavy loss from decay ; and perhaps not more than half the land in the country is suitable for the growth of the root.

Here every acre of land is suitable, and *planting can be carried on all the year round*, and consequently a regular supply can be kept up without the expense or risk of storing. There is a difficulty with young plants during the dry season, chiefly from the attacks of fly, but there are ... lies for this, besides there is little necessity for carrying on ... during the dry months, *the roots will stand on the ground ... damage for two years.* I have kept mangolds and beets on the farm land until they were two years old, and they were then quite sound, and weighed as much as forty pounds each.

The turnip, too, seems to accommodate itself to almost any elevation. I have seen them growing freely at Manantoddy, and they thrive at Bangalore, and at the top of Dodabetta.

I have written at this length on turnips, because I consider them the very back-bone of stock keeping, and if it is proved that the Hills are favorable for their growth, it is proved beyond dispute that it is, or

could be made a good meat-producing district. It may be said that turnips are not all that is required. Neither is it; we want fodder and cake. The latter I have already spoken of, and also grazing for store cattle. We still require fodder for fattening them. Here is what an English author says on the subject, "a cow or ox requires from two to three acres of pasture or meadow to feed it all the year round, but by raising clover, lucerne, saimpoar, or tares, three cows or more can be fed with the produce of one acre," and this, where for six months in the year growth is almost at a standstill, whereas here, with land under irrigation, growth goes on all the year round, and all the varieties mentioned thrive luxuriantly. Notwithstanding all this, we get on our tables quarters of mutton (?) of four pounds, and the remains of superannuated bandy bullocks

Reader, with a delicate stomach, do you purchase your own meat? If not do not venture on it. It is said that his Satanic Majesty provides us with cooks, and certainly some Demon, who presides over filth sends us our butchers. I should imagine they offer a premium for the dirtiest coolies they can find, to carry their meat to our doors. It is carried on a tray that has carried generations of bandy bullocks, without the purification of scraper or scrubber and is usually covered with a cloth that bears unmistakable evidence of having done duty as an article of dress. I see this, and still, thank God, for my daily food, but oh! how I would thank the man who would start some establishment from which I could obtain a well fed joint of meat, free from the abominations of filthy cloths and unwashed paws.

J. BARNARD.

KOTEGHUR NOTES.

SIR,—The weather has been extremely dry during this month: about half an inch of snow fell on the 15th, rain on the 20th and 21st, and a small quantity of hail on the 22nd, the whole barely sufficing to penetrate more than four or five inches into the soil. This dryness will stunt the wheat and barley, causing a loss in straw from the halms being so short.

The following is a comparative table of the past five seasons:—

	FEBRUARY.				
	1875.	1876.	1877.	1878.	1879.
Snowy days ..	8	[illegible]	5	1	1
Haily „ ..	..	..	1	6	2
Rainy „ .	2	6	1	[illegible]	2
	Damp and cold	First half fine, second half damp and cold.	Cold and damp. About 27 inches of snow fell	Mild at beginning, cold towards end.	Mild and very dry. Hardly half an inch of snow fell.

Wind at beginning of the month W. then veered to the N.-E.

Thermometer (Fht.), hung in open verandah W. aspect, about 42° in the morning, 50° in the evening, lowest 35° highest 51°.

Jungle-burning is still going on in those places where the villagers have more grazing ground than what they know what to do with. Where the grazing grounds are cropped for hay or eaten down by cattle and flocks these jungle fires never occur, it is only where the villagers have such a superabundance of grazing land that they cannot make use of it for their flocks and herds that they burn it: in Australia one acre of grazing land is reckoned ample to feed an animal all the year round.

The bark of the branches of the Kail trees (*Pinus excelsa*), in many places, has been covered with a kind of manna (vern. *Mereh*), it is sweet to the taste and is much liked by the inhabitants who go out in parties to obtain it, believing that good luck will ensue on eating it. It appears at long intervals of time and is said to betoken a hard winter and a season of scarcity. It comes out between the months of November and February. The last time it appeared was in November 1871. The Catkins of the willow (*Bushal, shun*) have budded, buds of the Andromeda ovalifolia (*Elan, erana*), wild pear (*shegul*), peach (*aru, beimi*) are swelling: plum trees (*alucha*) are now becoming covered with their pretty white blossoms, smelling so sweetly. Of wild flowers there are the rock lychnis (*d[illegible]mbú-lan*) with its red flowers; the violet coloured primrose (*fanting[illegible]*); and a small white flowered plant somewhat resembling the scented allysum in gardens. maiden-hair fern in warm moist situations.

The thrush (*bh[illegible]ru*), and starling (*[illegible]alar*) dart out of and about the hedges busy hunting for grub owls have come out from their winter resting places and bats also, the former are heard hooting in the jungle. The monaul, argus and other snow birds are now migrating (earlier than usual owing to mildness of season) to higher parts of the hills keeping just below the snow line; they are still tolerably tame. Hare hunting should now finish and the animals be left alone to mate, breed, and rear their young ones.

Food grains are now about as follows, per rupee, atta 8 seers, wheat 10 seers, coarse rice 8 seers, table rice 5 to 6 seers, corn dall 9 seers unground, or 8 seers ground, millets and inferior grains 12 seers. The dearness of provisions though partly due to the dry weather, we have now had for so many months, may also be partly accounted for by the fact that the local Government native officials are largely landowners, having large stocks of food grains on hand, and that human nature—where self interest is concerned—being selfish, it is only natural to suppose that rates for the food grains and other produce are being and will be driven up to their highest possible extent. Government though perfectly aware of the circumstance of the local officials being large landowners, yet keep them in their present positions "because being large landowners it would be an inconvenience to them to be removed," at least that was the reason given by the chief European district official, in one well known instance for not removing the naib tahsildar, when his removal had been recommended by a magistrate sitting on the bench and recorded in a judgment! Fancy retaining an European Government official in his position under similar circumstances!

Some of the villagers in the adjoining native territory of Kanayti have taken to ploughing their fields since the rain fell, with the intention of sowing corn and *barley* as they could not do so last autumn, through having but few ploughing cattle and their fields—the ones now being ploughed—becoming so dry, owing to the drought, before they could set to work upon them that they had to forego doing so; they are now hoping to recover lost opportunities and think that the present sowings' will ripen about a fortnight later than if sown at the usual time. I shall endeavour to keep myself informed of this experiment, and, if successful, I will keep a spare field and do the same next year.

Gardening operations much the same as last month. Zinia, mignonette, dianthus, and other flower seeds sown. Scarlet-runners sown during first week, sprouting in the last week. Transplanting of trees and shrubs going on. The vine which was transplanted during the frosty weather, has split and died down nearly to the roots [illegible] of that its period of removal was a little out of season, cuttings of roses, willow, &c, have been made and planted.

G. P. P.

Koteghur, 28th February 1879.

AGRICULTURE IN THE SARUN DISTRICT.

I.

SIR,—A great howl is raised against indigo in North Behar for taking up from 200,000 to 225,000 acres of land "which would otherwise be devoted to the growth of food-grain crops"; but when the crops in millions of acres of the very land which is entirely devoted to the production of food-grain, fail, then follow wild shouts for canals; and, as the late Colonel Gorbet remarked, engineering is asked to step in to take the place of agriculture. Experience gained during the present season of drought, however, conclusively proves to me that the true remedy lies in the ryots' hands, if it is made worth their while to take advantage of it. When the crops are parched and stunted, the cry for water at any price arises, and canals are considered the only panacea to mitigate the effects of drought. There are few men connected with agriculture in India who have not been stricken with this crave for canals; it originates with the first burst of alarm, and I am afraid that many people will succeed in ruining themselves, and their lands, before they discover the mistake committed in introducing canals to their districts. The project which is now being carried out in the Sarun district, presents a striking proof of how irrigationists would like to convert the most simple scheme into an elaborate work. All that the district planters asked for was a supply of water in the small rivers, which are now dry, and if the work had been entrusted to the charge of a committee of practical men, it would have been finished ere now, at a cost of not more than Rs. 1,50,000 at the outside. But the scheme has grown until it does not know itself; symmetrical cuts are being made across high lands; so, besides the cost of these works, the Government will probably have to pay heavy damages for crops ruined in water-logged lands, for it puzzles me greatly to think how maize, indigo, and the superior cereal crops are to thrive with stagnant water rotting their roots two feet from the surface of the ground. As it is, the spring level of the district is too high in many places during the rains, and even now in the month of January, in the vicinity of this factory, water is eight feet from the surface in high sandy fields, and 4½ feet in the very paddy *chours* which have failed to produce crops for the last few years. During the time crops were in the ground, water was only three feet from the surface in these *chours*, and yet the upper layer of pure impervious clay was compact and hard like blocks of stone. The soil in these fields at the present season cuts up in large lumps like coal, to a depth of three feet, until sand is met. This impervious layer prevents air making its way

through the soil, and also prevents the water from below rising to the surface by capillarity. There are, at least, two million acres of these stiff clays in North Behar, and during seasons of drought it might be said of the roots of the plants growing in these hide-bound soils, "moisture, moisture, *above and below*, but not a drop to drink." These lands are at present too strong, that is too say they have a layer two or three feet deep of the purest clay, which has been gradually washed down for centuries by surface drainage from the high lands. To improve the physical conditions of these clays, canal water is certainly *not* required, they want either lots of bulky organic manures, burning, or an admixture of sand to render them porous and friable; I have recommended the latter-mentioned method to the Government as the most simple and practicable in this country, where I despair of ever seeing the natives apply their straw in a rational way to the fields. Sand can be procured from the subsoil of the high fields or even a few feet below the surface of these very clays. Surface drainage from the high fields should be checked by enclosing them with banks, and by *cutcha* wells sunk in the lower ends of the fields; this would prevent the rain water sweeping down and lodging on the *chours*, which, after being rendered friable by any of the methods proposed above, will then be fit to produce all the superior kinds of crops grown on the high lands. The paddy is never a thoroughly successful crop, as it either suffers from droughts or floods; besides, under the most favourable circumstances, it is not so valuable as the highland crops. For the last eleven years I have had considerable experience of paddy cultivation under artificial irrigation, as a number of the *chours* in the vicinity of my factory are irrigated by natural flow when the Gunduck is in flood; and I have particularly noticed that the crops in those *chours*, which have been under irrigation for a number of years, do not present the same healthy appearance as paddy raised in seasons of heavy rainfall. The plants, too, often get choked by weeds, the seeds of which are brought down in the river water. It will sound strange to English ears, that, in places where irrigation water cannot reach by natural flow, the paddy crops have failed, although spring water was only three feet from the surface; but such has been the case with thousands of acres in every season of partial rainfall. Again, in seasons of heavy rainfall, when the paddy *chours* are flooded with rain and canal water, the maize crops suffer in proportion, *as the whole country then is water-logged*. I remember in 1871, a year of heavy rainfall, thousands of acres of Indian corn suffered from excess of moisture, and consequently distress occurred among the cultivators in many places. In friable and well drained soil the roots of the Indian corn plant average in length 5½ feet. A good idea of the condition of the crops in high lands, during the rains, can be gained by a study of the indigo *khoonties* (or second growth) during the months of August and September. The heavier the rainfall is, the poorer these *khoonties* are, and this is a proof that even the highest lands suffer from excessive moisture during that season. In 1871, when 69 inches of rain fell during the rains, the indigo second growth was so poor at my factory that it took 9 *beegahs* 13 *cottahs* of plant to fill a vat; whilst in 1877, when the rainfall was only 18·25 inches during these four months, the average per vat came to 3 *beegahs* 1 *cottah* of plant. Some people are too apt to look upon indigo as a dye, forgetting that it is a plant which thrives or languishes from the same causes that affect the maize or other high land cereal crops, and therefore when I bring indigo forward as an instance, I am often met with the reply, "that may be the case with indigo, but not with maize or other crops."

A most serious evil connected with land in which stagnant water lodges, is, that as it dries, the soil settles in such a compact form that the roots of plants cannot possibly travel in search of food; hence we find, in seasons of light rainfall, the paddy burnt and withered, although water may only be three or four feet from the surface of the land. If we insist upon bolstering up the paddy, we shall do so at the expense of the superior crops on the high lands, for the paddy does not thrive unless the lands are in a water-logged state; and this will be most suicidal policy when we take into consideration the fact that these very paddy fields can be improved so as to bear twice, nay three times as much food-grain, as they do now under the most favourable circumstances. The undermentioned statement should be enough to show the difference between a rational and vandalic system of agriculture. Fields 1 and 2 are within a stone's throw of a village near my factory, they are only separated from each other by a narrow border. No. 1 Field is farmed by a resident in the village, who has a number of cattle, the manure of which goes on to the land; growing high, dry crops as a rule, and being near the village, it also receives extraneous manures. These organic manures have rendered the clay soil friable and porous, and it produced an average of 28 maunds of maize per acre during last *khurreef* season; and now bears a flourishing crop of barley and mustard, the produce of which is estimated at 19 maunds of barley and 9 maunds of mustard seed per acre. This field, at all events, has done its duty in producing within a twelve month 47 maunds of food grain and 9 maunds of mustard seed per acre, *all without irrigation*. Now, let us see what field No. 2 has done. Being a little lower than field No. 1, the soil, in consequence, is a stiffer clay, and is devoted to paddy; it is farmed by a ryot who lives in another hamlet, a quarter of a mile off, hence the field is never manured. Paddy was planted in it; and although there were forty wet days, during the time it was in the ground, giving in all 26·60 inches of rain, still the crop proved a failure, and produced only an average of 5 maunds of unhusked rice per acre. The field is now empty, a hard impenetrable patch, devoid of weeds or vegetable life. The other day, at the beginning of this month, I took a spade, and digging through the hard dry clay came to *water* 4¼ feet from the surface. Now what would have been the effect of flooding this field? It would simply have raised the spring level to such a height that the maize crop in field No. 1, would only have produced half the amount it did when the spring level was lower; in fact paddy field No. 2 would have been nourished at the expense of maize field No. 1. The yield of 3,854 lbs. of food-grain per acre is of course enormous, and can only be produced from continuously and highly manured land; but it shows what this glorious land is capable of doing under proper treatment; and the paddy field, although not capable of producing the same amount for want of manure, would, if drained and rendered porous and friable, give at least 2,000 lbs. of grain per acre, as we know how prolific clays are under fair treatment. The maize crops this last autumn were very fair on the high friable loams, and the succeeding crops of *rubbee* were equally good, *without irrigation*, wherever manure was thrown; although, of course, in unmanured plots they are stunted and sickly. But is irrigation to take the place of proper tillage and manure? God preserve the people if it is. It strikes me as being most inconsistent to talk of 200 or 225,000 acres of indigo land (as the case may be) being "the curse of the country," when over two million acres of the finest land in the province annually produce next to nothing for want of proper treatment.

D. N. B.

II.

SIR,—My old employer used to assure me that a planter does not profit by experience until he has lost a lakh of rupees; using the same style of argument I may say that the Government of Bengal will not profit from warnings frequently held out to it until another famine, like that of 1770, desiccates the land and sweeps away 30 per cent. of the population. It exercises me greatly to think, why the Government should persist in patching and bolstering up a system of agriculture which has everything against it, and nothing to recommend it. If the paddy was a rich and prolific crop, like wheat or potatoes, I could understand the anxiety to keep it on its legs; but considering that when it succeeds best, it is at the expense of other crops and the cattle of the country, I think that the sooner its cultivation is confined to the very deepest *chowrs* in the province, the better it will be for the people and the land. If the cattle, like Balaam's ass, could only speak, I am certain they would tell us that they prefer a bad paddy season to a good one, as they then get clean sweet straw to eat; whilst on the other hand when the paddy lodges in the mud and water, the ears of grain are cut off, and the coarse, dirty straw, which is unfit for stock food, is left on the field to be carried off for the mere gathering, free of charge, by the saltpetre and *khari* makers. The cattle would also give vent to their feelings, very freely, with regard to the wholesale exportation of oilseeds which goes on from this province. I have a large stock of bullocks at this factory, and I find it impossible to get a sufficient quantity of linseed cake for them, although I am living in a country where flax is grown in every *rubbee* field. Most of the linseed is exported to Calcutta and other large towns, like fish to London from the provinces. With poor and lean cattle to drag our ploughs, and supply nothing but thin watery manure, it is impossible to expect the agriculture of the country to flourish, and I therefore beg of the Government to place a heavy export duty on oilseeds, so as to check the trade. The argument against interfering with free trade is no argument at all in this instance, as I am asking the Government to protect a wretchedly poor and ignorant peasantry against themselves. The people must manure their lands, and introduce a proper system of rotation of crops, or they will perish in millions; nothing but a sound and rational system of agriculture can save them. The last two seasons of drought have not passed without shedding certain advantages, as they have in the most prominent manner exposed the weak points in native agriculture; a painfully severe lesson to the wretched masses of the people, but one which our Government should be prepared to profit by. An almost insane confidence is placed in the saving powers of irrigation canals and wells by the Supreme Government, instead of these accessories being looked upon as one of the minor props to the prosperity of Indian

agriculture. Supplying India with irrigation works, without making an attempt to improve the agricultural practices, is like dosing a man suffering from *delirium tremens* with a bottle of brandy; for a short period these works *may* act as a stimulant, but eventually the last state of the land will be worse than the first. I claim every right to write as an authority on this subject with reference to my own province, as I have had a little irrigation work during the *khureef* and *rubbee* seasons all to myself for some years, and the more I study its effect on the cereal crops and opium the less I like it, even the very paddy crop is deteriorating under artificial irrigation. In September a heavy flood occurred on the Gunduck, and a large tract of country was submerged for many weeks; as the water dried up, the fields were sown down in barley and wheat. I said to myself as the men were sowing their crops—now is my chance of observing the fertilising properties of the Gunduck silt; but the result is most disappointing, the crops are thin and stunted, and the average yield will not exceed six or seven maunds of grain per acre. Certainly the crops were late in being sown, still they ought to be much better than they are. If irrigation can take the place of the rainfall, why has it not saved the poppy crops in Sarun during the last two seasons? It is not for want of trying that the natives lost their poppy, as they have been slaves to their fields ever since these crops were sown, working at the wells and ponds from morning till night, and many fields have received five waterings and as many more careful weedings. There is one field which I irrigated for the owner by natural flow, before the seed was sown, and since then it has received two or three waterings from well water, but the crops is miserable in the extreme and will not pay its expenses. On account of this unnecessary hard work and poor return, the poppy is becoming a most unpopular crop with the cultivators; and the Government should take warning in time, and ask the planters to institute a series of experiments to see if it cannot be rendered less precarious, as certainly irrigation alone will not save it. I have not seen any of Mr. Scott's valuable notes on the subject, but my idea is that the poppy fields should receive bulky organic manures such as refuse of indigo plant, and top dressings of rape and mustard cake, the seed also should be sown in trenches to protect the young plants from the extreme heat during October and the beginning of November. The loss of the revenue derived from the opium industry will be more than the Government could bear at present; but if the seasons do not change for the better, or an improved system is not introduced, the poppy cultivation in North Behar will become a thing of the past; for surely the Supreme Government will not force the ryots to continue the cultivation of the crop at a loss. If the opium department, at the end of the present season, will publish a statement showing the number of acres under cultivation, and each ryot's account for the last two seasons, the public will be greatly obliged. The Government owes a great deal to the ryots of this province for the opium revenue, and therefore it should be prepared to go hand in hand with the planters in introducing an improved system of agriculture.

The district officers of North Behar show by their statements, regarding the prospects of the cold weather crops, published in the *Calcutta Gazette*, how little they understand why the crops are so poor, as every reason but the right one is given. One gentleman says that "the cold weather crops on unirrigated lands are stunted and thin" and another that "the *rubbee* crops are poor for want of rain." If good crops of barley and wheat, which are suffering from over luxuriance of growth, were not to be seen in every pergunnah in *manured* and *unirrigated* lands, one would chime in with the idea that irrigation was necessary; but these manured lands prove that all that is wanted, even in dry reasons, for the *rubbee* is organic manure in the soil. Certainly the *rubbee* is very poor in unmanured lands, "sick unto death" for want of sustenance; but the manured and unirrigated fields show crops which would do credit to any country, if rape and mustard had not been mixed with them. At the same time I can point out thousands of acres of irrigated *rubbee* which have not benefited from irrigation in any way, although the season has been such a dry one. The clay soils of the low lands, and the sandy loams of the high lands, in North Behar are homogeneous in character, and are simply influenced by the treatment they receive. The best land is the land which receives the best treatment; for instance, a field may be seen with a crop which promises 20 maunds of grain per acre, whilst alongside that very field will be found a crop of the same description that will not give 3 maunds per acre. It is hard to blame the land under these circumstances. Suppose a man to have a spirited thorough-bred horse; he starves that horse, and then rides it at full gallop in its exhausted state:—what are the consequences? The animal probably falls and kills his rider. But who is to blame under these circumstances, the horse or the man?

These dry seasons prove how organic manures [illegible] the crops, and at once point to these manures as being the best suited to this climate. I can show wheat 5 feet high; oats 5½ feet high; garden peas 7 and 8 feet high; turnips weighing three pounds each; all raised during this season on organic manures without a drop of irrigation water. And during last year, a season of scarcity and famine, Mr. Macdonald of Pertabpur factory lifted an average of 340 maunds of potatoes per acre from high sandy land manured with *seet* water; this is very encouraging, and shows that the soil is capable of great results; I should like to know if any other planter has experimented with *seet* water as a manure for potatoes.

The fact of planters wanting water for irrigation, during seasons of drought, in the hot months of March and April, when all the superior cereal crops are off the ground, does not go to show that irrigation is required for the *rubbee*. If the planters sowed their indigo in October when the *rubbee* is sown, or in June when the maize is sown, the Government would hear very little about irrigation in North Behar. Irrigation is certainly required for the paddy, but this crop is not happy unless the fields are flooded, and this condition of things is against all sound agricultural practises, as flooding and water-logging half the lands of a country for the benefit of one particular crop must injure the "dry" crops on the other half. The very fact of oats succeeding so well in these districts without irrigation should be enough to show that it is not required for the *rubbee*, as even in England oats require a damp climate. The planter in these districts who has once irrigated well manured wheat will not repeat the mistake a second time, unless he wants the crop to be ruined by mildew and rust. I may be thought guilty of exaggeration in making these statements to prove my arguments; but the field and their crops do not exaggerate, and will prove all that I say.

Now, although I am greatly opposed to irrigation for the *rubbee* crops, and hold that the *paddy chowrs* should be reclaimed and rendered fit to produce to perfection such crops as sugar cane, wheat, and barley; still I say that cultivation should be prohibited in the natural drainage channels of the country, and these *nullahs* should be deepened, embanked, and supplied with water from the big rivers so as to render them navigable. I put the question to the public: which is best suited to the country, a network of navigable *nullahs*, or a network of *cutcha* roads? The *nullahs* in this district were navigable eighty or a hundred years ago; and I do not see why they should not be rendered navigable again. The *cutcha* roads as they exist at present do the British sense of justice no credit. One of these roads presents the appearance of three roads running parallel to each other, the middle road being reserved for *ekkas* and carriages, and the two side roads devoted to the carts of the poor wretches who pay the roads cess. These roads are a great deal too wide, a great deal of valuable ground is wasted by the side cuttings, cart tracks, and big road in the middle; the side-roads and cuttings should be let out for cultivation to the ryots, on the understanding, that instead of paying rent each ryot keeps his part of the main road in thorough repair; this proposal would be greedily jumped at by the ryots. There would then be one road for all, the roads would be kept in thorough repair without costing a pice, and the rich road cess funds might be devoted to making our *nullahs* navigable. A network of navigable *nullahs* in the province will give us back the cheapest form of transport in the country; and besides helping to change the climate they will also supply the inhabitants with abundance of fish, which will swarm in the small rivers whence they can run backwards and forwards between the big Gunduck, Gogra and Ganges. There should not be locks on any one of the *nullahs*, as they would interfere with the fisheries, and raise the spring level of the country to an injurious height. The villages might be entrusted to deepen the *nullahs* at one half the amount, outside contractors would charge.

Before finishing this letter, I must touch on the great advantages which would accrue to the ryots if oil-mills were set up at every factory. Organic manure is the principal thing the land wants to enable it to produce crops sufficient to support the people, and we cannot expect to get this manure to perfection if the cattle of the country are badly fed. Do what we will by opening out the country with railways and navigable canals, but famine will always haunt the villages until the native do justice to their cattle and their lands.

D. N. R.

THE SUGAR INDUSTRY AT MACKAY, QUEENSLAND.

SIR,—It is now fourteen years since Mr. Spiller left Java and arrived at Mackay with a quantity of sugar canes for acclimatisation and if possible in due time to make sugar. The progress the sugar industry has made during the last ten years entitles it to be ranked as one of the firmly established industries of Queensland.

Mackay lies fairly within the tropics with a climate decidedly favorable to sugar-growing. Frost so dangerous an enemy to the sugar planters at Maryboro' and on the Logan, occurs very rarely

here; it has only once been known to be so severe as to harm the crop, but even then the damage done was very slight and only such cane suffered as grew in the deeper hollows of the undulatory land. The position of the greater part of the Mackay district lying on the sea coast and moreover surrounded as it is by high hills and possessing also many in its midst, all of which are more or less covered with a thick vegetation of a jungle character, ensures a regular supply of rain, the greater part of which falls during the rainy season commencing towards the end of December and continuing until the end of March. Hitherto the cane has never suffered from an absolute want of rain, although last year more rain than actually fell would have been more favorable to the crop. From the luxuriant growth of the cane as well as other plants one concludes that the soil is very rich even when taking into consideration that moisture and a high temperature tend to luxuriance of growth. The soil possesses but little lime. There are two varieties of soil here are on which cane is grown; one a very deep vegetable mould, the other a loam with stiff clay subsoil, but which, when well and deeply stirred and bedded, produces cane almost as good as the former does. The other soils vary much between these two.

Table I, gives the average temperature and rainfall as observed at Alexandra Plantation during the last eight years; this plantation is situated some seven miles inland on the Pioneer river.

TABLE 1.

	Temperature.		Rainfall.	
	M. Max.	M. Min.	No. of D.	Inches.
January	95·2	68·7	17	18·38
February	90 2	68·1	15	13 37
March	88·0	60·5	10	10·67
April	86·3	59·0	8	7·16
May	78·5	51·6	9	5·81
June	77·3	46·8	7	2·44

The first mill was erected by Mr. Davidson at Alexandra Plantation and in 1867 about twelve tons of sugar were made there. Messrs. Hewitt & Co. followed suit in 1868 and since then until the fatal disease year 1875 the number of mills increased rapidly.

In 1870 there were 4 mills with 2 stills.
,, 1871 ditto 10 ditto ,, ,,
,, 1872 ditto 14 ditto ,, ,,
,, 1873 ditto 15 ditto 3 ,,
,, 1874 ditto 17 ditto ,, ,,

The prospects of the industry were probably never brighter than in 1874, but in 1875 its progress was suddenly checked by the appearance throughout the Colony of that terrible disease in the cane, commonly known as rust. The origin and development of this disease are still not fully accounted for. Its first appearance was after an excessively heavy fall of rain. At first it was said to be a fungoid growth, later on it was found that the ravages of the fungus were augmented by myriads of *acari*, and now from the very latest information it would appear that the *acari* are probably the primary cause of the disease.

There are at present sixteen mills working at Mackay on their respective plantations (besides a few small plantations which sell their produce to the mills), as follows:—

TABLE II.

Plantation.	Owner.	Produce.
		Tons.
The River Estate	Spiller	900
Branscombe	Maitland King	400
Pleystowe	Hewitt and Romilly ...	450
Te Kowai	Sloane and Co.	1,000
The Cedars	,, (?)	250
Nebia	,, ...	300
Inverness	Geo. Raff	250
Cassada	Donaldson	180
The Alexandra	Davidson	450
The Pioneer	Spiller	800
Meadowlands and Balmoral ...	Hyne	650
Barrie	Sloane and Co. (?) ...	240
Foulden	F. T. Amhurst	550
Miclere	Carrol and Avery... ...	250
Dunbleton	Sloane and Co. (?) ...	240

Five of these mills, namely Foulden, Meadowlands, Pioneer, River and Te Kowai, boil their sugar in vacuum pans.

The average production per acre of cane crushed is as follows:—

TABLE III.

Season ending 31st March.	Tons.	Cwt.	Qrs.	Lbs.	
1872	1	10	0	22	
1873	1	6	3	19	
1874	1	8	2	5	
1875	1	17	2	14	
1876	0	14	3	2	} Effects of rust.
1877	0	18	3	14	} Effects of rust.
1878	1	10	2	6*	

Until the rust made its appearance, the Bourbon cane was the variety universally planted, since then many hardy and so far rust-proof varieties have been introduced. Those mostly met with now are, Big Yellow Meera, Black Java, Rose Bamboo, Otamatie and Gingham; in smaller quantities are also grown Caledonian Ribbon, Ireboe, Malabar and others.

The canes are not ratooned more than once, unless the first ratoons turn out exceptionally good, when occasionally they are left to ratoon a second time.

The Icery process as introduced in the Colony by Mr. DeLissa, the colonial patentee, was attempted at the Pioneer plantation, but the results did not prove sufficiently satisfactory to warrant its establishment.

At Foulden, Mr. Robert Walker, manager, a refining process has for some years been in operation, which produces one of the whitest and most perfect sugars I have ever seen turned out by a sugar mill. This process has not been introduced on any other estate, probably because it is said to be very expensive.

Sugar planters calculate upon receiving £25 per ton all round on their sugars, less *working* and *shipping* expenses.

The three mills to which stills are attached are the Alexandra, Pleystowe and Te Kowai. The "Anchor" rum produced at Pleystowe is a very superior spirit and commands the best price amongst the colonial rums.

The amount of spirit produced at the above named stills during the the season ending 31st March 1878 was 95,898 gallons which coming from 145,255 gallons of molasses gives 1½ per proof gallon; these figures compare favourably with the results obtained in the south where 2½ and 2 are the ratios. At Mackay the distillers complain that they cannot get a sufficient quantity of molasses.

Finally the prospects for next crushing season are excellent. A larger area of land is under cultivation than hitherto, and one of the planters is about to enlarge his mill in order to be able to crush cane from the many small farmers in the district. Should the cane still remain free from rust and the weather continue as favorable as hitherto, the crushing season of 1879 will prove memorable in the annals of the Mackay Sugar Industry.

HENRY LING ROTH.

Brisbane, Queensland, 29th Jan. 1879.

THE WILD OLIVE IN BURMAH.

(*To the Editor of the Madras Mail.*)

Sir,—In your issue of the 5th ultimo, I find that you publish "the discovery of the wild olive in Burmah." Several parties here have been mentioned, and each one declares that the merit of the discovery belongs to him alone, and the authorities and the public have been led to believe in a mine of wealth, that will prove more profitable than all the gold fields of Wynaad. So no wonder, that all Burmah "tuck it down like tracle," and licked their lips over it, till a letter appeared in the Rangoon *Gazette*, signed *Agricola*, in which the writer stated that this wonderful "Burmah olive" grew wild from one end of India to the other; the natives in some parts making a kind of arrack from the flower, called "Smoky Jack," while the oil from the seed gave *more smoke* than light. Throughout the Madras Presidency, it is known in Tamil, as "Illapay"; and by the Teloogoos, as "Ippay," while from Orissa, in Ganjam, and through all Bengal, it is also known. Look at any Price Current or Customs Statistics, and I am sure you will not be able to find the seed or the oil of this famed olive quoted, as an article of export; and if this is so with regard to India, where the tree grows wild, and where labour, is so cheap, how is it possible that any one in Burmah investing in such an undertaking can ever expect to realise a single fraction of their outlay, when an ordinary cooly turns up his nose at an offer of Rs. 10 a month, and where the Burman will not work for you! But supposing for an instant that the tree will answer all the expectations formed of it, what then? Will Burmah stand the least chance with India in the markets? Certainly not; the planters in Wynaad would be able to plant the whole of that district with it, and export it at a quarter of the cost, which one would incur in Burmah

During all my stay in Wynaad, I never saw the people make any use of either flower or seed. Hoping none of your readers will be gulled as the Anglo-Burmese appear to have been.

OBSERVER.

The Indian Agriculturist.

CALCUTTA, APRIL 1, 1879.

THE BAMIEH COTTON PLANT.

THE endeavours that were made during the last two years, to introduce the Bamieh cotton plant into India, have on the whole been fairly successful, inasmuch as it was shown that the climate and soil of different parts of India are suitable for its cultivation; but a great doubt exists in our mind as to whether the *bulk* of the seed received in India was really Bamieh cotton, as there is a great deal of evidence forthcoming which shows that the majority of plants raised from the seed possessed none of the peculiarities that distinguish the Bamieh cotton plant from the ordinary Egyptian cotton.

This new and important species of cotton was discovered by a Copt in the Nile Delta neart he Cairo Railway, in the province of Menúfié, in 1873. The Copt noticed a plant in a cotton field, wholly different from the rest, and carefully collected the pods, separated the seed and planted it secretly in an isolated plot of ground. He carried on the cultivation of this new cotton for three years, before general attention was drawn to it. For the last two years the area in Egypt under Bamieh cotton, has largely increased and its cultivation is sedulously promoted by the Minister of Agriculture; it has been calculated that there will be sufficient seed available this year, to cover with Bamieh cotton the whole area that is fit for cotton cultivation in Egypt, amounting to about 700,000 jeddans (350,000 acres). The importance that attaches itself to the cultivation of this new species, consists in its yielding per same area, nearly three times as much cotton as the ordinary cotton plant. The Bamieh cotton plant has straight stems, attaining a height of nine to ten feet, and instead of throwing out lateral branches, produces two or three semi-verticillated pods, issuing directly from the axilla of each leaf, these being alternately arranged around the stem.

The ordinary Egyptian cotton plant, on the other hand, (in its varieties; *Mako-Jumel Gallini, Ashmúni, etc.*), has the form of a shrub, with one or more main stems throwing out numerous lateral branches, which occasionally spread out to a considerable breadth and bear pods at various intervals, two, three or even four leaves often producing no pods from their axilla. The leaves of the Bamieh cotton plant are large, greatly undulated, and of a deeper green than those of the ordinary cotton. Its flowers are yellow, the interior spotted with purple somewhat like those of ordinary cotton, but they are frequently larger-sized, and grow on elongated peduncles.

As to its origin, it is thought that the contact of Bamieh plants, which existed in the cotton plantation of Birket-el-sab, having produced this new type, acted upon the seed of the cotton plants at flowering time, and that the origin of this species may therefore be attributed to a process of hybridisation between the Bamieh (*Hibiscus esculentus*) and the ordinary cotton (*Gossypium barbadense*), the more so as, when seen from a distance, plantations of this new cotton display, like those of the Bamieh, (*Hibiscus esculentus*) a multitude of high, straight stems without branches, at least as regards three-fourths of their length from the tops. If it be true that the new Egyptian cotton is the result of hybridisation between the two species above named, the fact is one of great importance to science, because in the annals of horticulture, the process between species differing so widely is rare enough, and because such results as have been recorded down to the present time have generally remained sterile, or at best but of little use in the sequel; whereas in this case Nature has produced a more fertile cotton than the ordinary kind.

The "Bamieh," we may mention, is the plant known to us in India as the *Bhendi* and *Rainturai.*

Seed of the Bamieh cotton plant was obtained in 1877, by the Government of India, by the Agri-Horticultural Society of India, by Messrs. W. Nicol & Co. and several others. The seed imported by Messrs. W. Nicol & Co. was sent to their mofussil branches in Guzerat, and in November 1877 we heard that there was about an acre of land under cultivation with this cotton, one half of the land being irrigated and the other left to the action of the ordinary rains. The results of this experiment are not known to us though we have made some enquiries regarding it. The Agri-Horticultural Society grew from the seed it received a few plants in their own garden at Alipore, and distributed the rest to the Governments of Bengal, the N.-W. Provinces and private individuals.

In the Society's Garden at Alipore, the seed that was sown in the middle of June 1877, grew vigorously to ten feet in height, began to blossom in September and the plants yielded their first ripe pods in October and November. In April of the following year (1878) it recommenced to flower, and it was proposed to allow the plants to remain as biennials, in order to ascertain if the quality of the next season's produce would retain its character or deteriorate.

From the seed sent to the N.-W. Provinces, a small quantity was sown at the Experimental Farm at Cawnpore, on the ridge system. Of 20 seeds sown, 13 germinated. They were sown in July; first bolls were picked on 20th December; yield of the 13 plants five pounds Kapas (uncleaned cotton), of which four and a half pound on being passed through the native *churka*, yielded 22 ounces of clean cotton and 3 lbs. 2 oz. of seed. The plants were grown 2½ feet apart, and threw out long lateral branches, a few of the plants only being of tall upright growth with few side branches. Mr. Buck observed the distinction between these few plants and the rest, and has gathered the cotton and seed separately and has called that, obtained from what appeared to him the true Bamieh cotton plant, No. 1, and what appeared to him the ordinary Egyptian cotton, No. 2.

Mr. W. Masters, of the Opium Department, at Hadjepore, also grew a few plants and reports the plants as having a main stem, ten feet high, with lateral branches, issuing from it within the space of a foot and a half from the ground.

Messrs. Haworth and Co., of Calcutta, report on this cotton, grown as above, as follows:—

1 Bolls similar to Egyptian cultivation, and like it as regards its seed, both as to formation and freedom with which the fibre can be separated. (*Cawnpore Model Farm*)

2. Not of a particularly good color, but as regards length, softness, strength and fineness of staple, every thing that "could be desired, and would rank as good fair, Egyptian cotton, valued at about 7 to 7½ per pound." (*Ditto*).

3. Not equal to No. 1, either in size of the boll or the quality of the cotton, but similar in all other respects. (*Mr. Masters*).

4. Equal in color to No. 2, but containing considerably more stains, harsher in staple, which is also wanting in length and strength: value about 6 to 6½ per pound. (*A. H. Society's Garden.*)

The agent of the Elgin Cotton Mills at Cawnpore thinks the staple of the Cawnpore-grown cotton particularly fine

and equal to cotton used in England for the spinning of yarn of counts ranging between hundreds and two hundreds, and estimates its probable value in England at a shilling a pound. The same cotton was reported on by Mr. C. Kapp, one of the most competent judges in Bombay, at the request of the Secretary to the Chamber of Commerce, as follows :—

"I have received your note and a sample of cotton. After examining the latter carefully, I have come to the conclusion that the nearest comparison in appearance and touch to it is fully good fair brown Egyptian cotton. The staple is silky, but very irregular and very wasty, which deficiency would debar this style of cotton from being mixed together with Egyptian, or used separately for high numbers. Besides the irregularity in the staple, there are very objectionable knots and nests in it, which reduce the value of the cotton. Taking into consideration that the price of Egyptian cotton is exceptionally high now, and fully good fair brown being quoted about 9½*d*. I value the sample at ½*d*. below that class of cotton, say 9¼*d*. If the cotton has not been allowed to mature fully, this circumstance might account to some extent for the wasty staple, but even admitting that some of it has been picked in an unripe condition, the best of it would not be worth more than 9¼*d*. which would be equal to good brown Egyptian."

The details of the experimental cultivation of this new species at the Bhadgaon Government Farm, Kandeish, marred greatly by the adverse season, were published in our last issue. Mr. Stormont states that he finds little difference between it and the ordinary Egyptian cotton. The resulting fibre was submitted by Government to the Bengal Chamber of Commerce who report :—

"The staple is long and strong; the cotton is clean and very free from stain, and the colour and general characteristics are those which belong to cotton grown in Egypt.

The Committee of the Chamber are of opinion that if the quality were kept up to the sample before them, and spinners could depend on a certain regular supply, this description would in process of time come to compete side by side with Egyptian and the better qualities of Brazils in the home markets.

It is very superior to any Surats yet exported, and till it becomes known and appreciated, it is difficult to fix the value. The Committee think, however, they may roughly quote it to-day at Rs. 20 to 21 per maund, or to sell in Liverpool 5¼ to 5½ per lb."

If we read, in conjunction with the above, the report on the Bamieh cotton plant furnished to the Egyptian Ministry of Agriculture by Monsieur Delchevalerie, we can but come to the conclusion that the seed received in India in 1877, was not pure Bamieh cotton seed, but was adulterated and, if not entirely consisting of the ordinary Egyptian cotton, was so largely mixed with it, that on this account the experiments cannot be pronounced as decisive; and we can only hope that the further supply of seed (12 pounds) which the A. and H. Society received last June from Mr. Chapman, the agent of the P. and O. Co., at Alexandria, will turn out better.

The following details of an experimental cultivation of this cotton, which was made in Texas in 1877, is taken from our contemporary *Cotton*, and will be found interesting :—

"The seeds were planted on 4th May, in a garden situated in lat. 29° 40′ at an elevation of thirty feet above Galveston Bay, and about 800 yards from its margin. The soil was a light, fertile, sandy loam. The seeds germinated, and the plants made their appearance above the surface of the soil in six days, namely, on 10th May. The first blossoms appeared on 8th July, and the first open fruits on 30th August. The average height of the plants was about eight feet, but some grew up to ten feet. After the plants had ceased growing the fruits perfected themselves, increasing in size. It is stated that the fruits are very abundantly produced from near the base of the plant to its very top. In the space of four months and ten days from the time of planting, the open fruits were of sufficient size for picking in any quantity. From as careful and safe an estimate as could be made, the yield was found to be fully equal to 2,500 lbs. of cotton in the seed per acre. The habit of the plant is described as being very singular in its outline. Unlike the American Upland, and Sea Island cottons it does not send off branches regularly from near the ground to the top of the plant; but the main stem bears close to the ground two, three, or more branches, and then rises to a height of eight or ten feet without a branch. Leaves only are given off along the stems, and in the axil of each leaf are from two to five, and sometimes six long petioles each bearing a fruit. The branches described at the base were also very heavily fruited, as many as five large fruits growing so close together as to touch each other. The cotton or wool contained in every fruit on the plantation was of a pale yellow color, which was difficult to be accounted for, as there had been no heavy rains during its growth to stain it; it it is suggested the profuse dews may have been the cause. From the record of these experiments it seems that we may still hear something favorable, about Bamieh cotton with regard to its becoming an article of commerce."

CULTIVATION AND MANUFACTURE OF TEA.*

UNDER the above title, Colonel Money has published the third edition of his Essay on Tea, which received the Grant gold medal and a prize of Rs. 300 from the Agri-Horticultural Society of India in 1872. Circumstances have considerably altered since then; our knowledge of tea has been considerably enlarged and added to, during the six years that have elapsed. Managers of tea estates are drawn now from a more intelligent class of men, and altogether, with the exception, and it is a very great one, of manuring, there is little in the practice of cultivating and manufacturing tea, as practised in most of the well managed estates of Upper and Eastern India, that is open to any great improvement. Colonel Money has advanced with the times, and the work under review may well be considered a standard work on the Cultivation and Manufacture of Tea, which ought to be in every tea planter's library in India, Ceylon, Java, Japan, China or America. The merit and sterling value of his first essay has been so universally and deservedly acknowledged, that all that is left for us to say is, that this, the third edition, contains all the additional information that has been gained during the last six years, has been corrected up to date, and much enlarged. The value of Colonel Money's work is enhanced by the fact, that he has seen and studied tea cultivation in most of the districts of which he treats, and that he deals with the whole subject in a practical manner, and has very few scientific theories to advance. Our space does not permit us to do more than briefly notice the principal points and features of Colonel Money's book.

Colonel Money defines in the first seven chapters the conditions requisite for success in tea cultivation. He is of opinion, and experience supports him, that on a suitable site, and in a good tea climate, tea will pay; it is equally certain that it will be unsuccessful in a bad locality and on unsuitable sites. No garden should exceed 500 acres under tea, and if highly cultivated, Colonel Money says, even half that size will pay better than a larger area with low cultivation. This is, of course, excluding such land as should be reserved as forest lands. In fixing on any district to plant tea in, four things have to be considered, *viz*, climate, means of transport, labour and soil. The climate required for tea is a hot damp one, the rain-fall should not be less than 80 to 100 inches per annum and should be well spread over the year. The plant will certainly grow at a great elevation, and even at freezing-point. But the flushes of leaf there are less frequent, and the manufactured article has less strength. Tea flourishes to far greater advantage where there is hot sunshine, copious rain, especially in the early part of the year, and rich soil. Drought shrivels up the leaf; cold stops its growth. The drier climate of the North-Western Provinces is far inferior to the moisture and heat of Assam. Colonel Money, in Chapter III, puts the tea-growing districts or provinces of India through a sort of competitive examination, in which the subjects selected are climate, labour, lie of land, soil,

* *The Cultivation and Manufacture of Tea*, by Lieut.-Colonel Edward Money. Third edition, corrected and much enlarged. Calcutta: Thacker & Co.

and transport; and then adjudges the prizes to Assam, Cachar, Chittagong and the Western or Bhootan Doars. Kangra, Kumaon, the Dhoon, and the Neilgherries, though charming for invalids enervated by long residence in the plains, are prejudicial to the tea plant as far as quantity of outturn is concerned; for the Kangra valley teas as regards quality excel in delicacy of flavour any other Indian teas. Assam and the Terai are first and second in this part of the schedule.

We have already referred to the size of a garden, as recommended by Colonel Money. A very large acreage means heavy expenditure with disproportionate yield. An estate of 3 to 500 acres, in full bearing, where there are no "vacancies," with a good site, cheap labour, facilities for manure and ready transport, will yield a more certain and a larger return than a vast area badly chosen and not highly cultivated.

Tea luxuriates in friable soils, with a sandy or loamy subsoil; light coloured loamy soils or sandy loams, containing 5 to 10 per cent. of organic matter in the upper layer being preferable. Stiff soils of every kind ought to be avoided and no matter how light and friable the surface soil, if the subsoil is clay, the site is not suited for tea cultivation. Forest and grass lands are equally suitable. The "lay of land," is a subject on which Colonel Money speaks very lucidly. In the Himalayas for instance the warmer aspects are, as a rule, the most fertile: *vice versa* in warm climates. There are few if any planters now, we think, who would dream of laying out a garden on *steep* slopes, experience having shown that even where terracing was tried, the surface soil was gradually washed away into the valley below. Gently sloping valleys or table lands, are the choicest sites for a tea plantation. In Chapter VIII, the advantages of dividing gardens into sections of 5 acres each are set forth, the chief of them being that each section can be treated, regarding plucking, as an independent portion from the rest. Only where the soil all over the garden is the same, and observation shows that it flushes equally, it may be left all in one. In the Chapter on "Tea Seed," sufficient stress is not, we think, laid upon the advisability of gathering seed *only* from tea plants that have been allowed, for a couple of years at least, to grow naturally without plucking or pruning. We hold that seed collected from plants that are regularly plucked, is degenerated and ought never to be used for seedlings.

Regarding sowing in nurseries or *in situ*, Colonel Money says that where planting *in situ* will succeed, it is by far the cheapest and best, but it will only succeed, where there are cold weather and spring rains, and even in those climates success is not certain, as the early rains often fail, so that in all cases nurseries in reserve are advisable. Chapter XII and XIII give detailed and clear instructions how to raise plants *in situ*, and in nurseries.

Regarding manuring Colonel Money says:—

"My first experience of manure to the tea plant was obtained in the Chittagong district from a small garden close to the station, which has been for some years highly manured. I was struck with the frequency and abundance of the flushes and the strength and flavour of the tea. My high opinion of the tea was later borne out by the Calcutta brokers. I allude to the 'Pioneer' garden, close to the Chittagong station. During the best tea months, flush succeeded flush at intervals of less than a week, while 8 to 10 maunds (640 to 800 lbs.) was the yearly yield per acre! The soil was very sandy and poor.

After-experience showed me that manuring nearly doubles the yield of plants, and that so far from injuring the flavour of tea it improves it while it adds greatly to the strength.

I shall therefore beg the question that manure is an advantage. If any planter doubts let him try it, and his doubts, will soon be solved."

We take exception to Colonel Money's advice to bury garden refuse and prunings in a *green* state between the plants. This is an objectionable practice, being certain to encourage the propagation and development of the fungoid and animal parasites, comprised under tea blights. The researches made in Ceylon, have given full and clear evidence of this. The garden refuse and pruning, we advise on the contrary, should be collected in large manure heaps, their decomposition should be hastened by an admixture of caustic lime, and they should be covered with a layer of soil, to be kept moist, so as to absorb the ammoniacal gases of decomposition.

In planting out a garden, 4 to 4½ feet is considered by Colonel Money the best distance between the lines, the object being to place as many plants on the land as it will bear, and leaving yet sufficient space for cultivation between the lines. Chapters XVI and XVII are taken up with advice, how to make a garden and how to transplant the seedlings; attention is drawn there to Mr. Jeben's transplanting and transporting tool, regarding which an independent planter writes: "No manager of a tea or coffee plantation, who had once seen this instrument at work, would ever again be likely to recur to transplanting by hand." Colonel Money considers this invention, a most important one. Space does not permit us to follow Colonel Money through the remaining chapters treating on the cultivation, pruning and plucking of *made* gardens, and their treatment generally, as well as on the manufacture, sifting, sorting and packing of the tea, on all of which subjects he speaks with great experience and advances valuable suggestions for improvements. Nor can we follow him through the chapters on the management of tea gardens generally, on the cost of manufacture, cost of making a garden, the profit tea can give and his concluding chapter on the "Past, Present and Future of Indian Tea," subjects which are treated by him in an equally lucid and authoritative manner, but we recommend our readers who desire full information and sound advice on the above, to peruse Colonel Money's book, which must undoubtedly be considered a standard work on "The Cultivation and Manufacture of Tea."

INDIAN RIVERS.

INDIA presents many fierce contrasts to England; but perhaps in nothing more strongly than in her rivers. The name of an English river calls forth all pleasant summer thoughts, and sweet images of shade and soft turf, and green leaves, and glancing water. The Indian river, at its best, has no such associations. Hill streams are sometimes pretty and picturesque, though rolling through rocky wildernesses to which the grace of moss and heather has been denied; and though the most that can be said of them is that they serve to remind the traveller of more lovely and familiar scenes left behind. But what shall a man say of the rivers of the plains? The theme is not one in itself devoid of beauty and charm. A great English poet, imagining pictures for his soul's delight, chose to adorn his fabled Palace of Art with the likeness of—

> A full-fed river, winding slow,
> Through herds upon an endless plain;

ever as Homer wrought the same picture by Vulcan's hand upon the shield of Achilles, to signify the happy pastoral life, with its wealth and quietness and peace. Alas, the Indian river, albeit winding through an endless plain, is no more full-fed than the herds upon its banks. It takes one of two shapes. The less common is that of a tortuous muddy ditch, brimful, indeed, in the rainy season, and for some short time after not wanting in a fair supply of water, tolerably clear; but soon shrinking, summer-dried, when men's need is the sorest, into a stagnant canal, foul, choked with weeds, and deep sunk below the level of the parching fields. Or, if the water be stopped by a dam, and made to give life and brightness for some few miles above, nothing can be more forlorn than the wanderings of the dry channel below, as it twists aimlessly through the land, filling the air with the sick smell of aquatic plants perishing under the pestilent sun. The other type of river is one which fails not for water, but its surroundings are the abomination of desolation. Little need is there to recall the picture, familiar to every sojourner in this country, of the inhospitable wastes

which spread around the course of the historic streams of India and all their major affluents. The river makes known its presence from afar, by the bright gleam reflected from many a mile of hot dazzling sand, through which man and beast plod heavily on to the margin of a deep, rapid, turbid stream, some few score yards broad, flowing close under a high bank of clay, into which it is for ever eating, and the plash of falling fragments is the only sound heard along its melancholy banks. No trace is here of the "glassy, cool, translucent wave," nor any of those pleasant things which have in all ages drawn Western poets to the riverside for inspiration. The myths of the East assign a hideous origin to the Father of Indian waters. He comes tumbling from the interminable unkempt locks of Siva, the Destroyer, bringing with him all his train of alligators, crocodiles, turtles, water snakes, and whatever other noisome and loathsome creature rejoices in his sacred stream. The gaping mouth and serrated back of a huge lizard, or the round shell of a great tortoise, fed on corpses, or perhaps the corpse itself, drifting hopelessly down the mid-channel or stranded on a shallow, and covered with gorging vultures—these are the sights which enliven the Ganges strand by day, and at night, near large cities, the course of the river may be tracked by the glare of funeral fires. Nothing more depressing can be imagined than an evening ride over the river sands in the sultry time of the year. In the rains, all this is a waste of waters, too dull and turbid to lend any charm to the landscape, while swift currents and sudden blasts make it useless, and indeed dangerous, for the boating which its wide expanse seems to invite.

If the objectionable points of Indian rivers, however, were of a merely sentimental character, one might be content to leave them alone. But there are other bad qualities which give a deal of trouble of a much more practical nature. The river, in the pride of its floods, has a tendency to sweep the works of man off the face of the earth. Every one knows the story of the difficulties attending the construction of all our large Indian bridges. Without mentioning such giants as the Sutlej or the Ganges, one may quote a piece of experience from the Ramgunga, a river of the second class, which was forced to submit to a bridge some six years ago. It did not yield without a struggle. The piers had been sunk to a depth of seventy feet, and then the floods came, and when they sank, the massive pillars were found lying under hundreds of tons of sand, in the river bed, carried by some unaccountable current several yards up the stream. The railway now travels over piers which rise thirty feet above the water, and reach down a hundred feet below it. If these things happen to vast viaducts, one can easily guess the fate of villages which stand in the way of the stream. The loss of personal property, indeed, is not much; for the village rose out of the soil and sinks unregretted into it again, while there has usually been ample warning for the removal of the few brass dishes which are the Indian peasant's household goods. But the loss of the village lands is a more serious matter. So long as the process of destruction is gradual, the hardship is less felt. The cultivator has time to look about for land elsewhere, and he will not throw away his seed upon a field which seems likely to fall into the river as soon as the rains begin. But a few years of gradual erosion are often succeeded by a sudden change, transforming all the riverine topography, and throwing hundreds of acres out of cultivation in a single night. It is not merely that the river has struck out a new course, leaving the old bed dry, and the surrounding country as it was before, except that a certain number of fields have been appropriated for the new channel. That would be a small matter, of which nobody need complain. But the truth is that the river, as it advances in its process of erosion, leaves behind it only stretches of barren sand; and when a sudden change comes, the utmost gain to the adjacent villages is that this unfruitful tract is secured to them, safe from fluvial action for a term of years, in the place of the good land which was swallowed up, digested, and then voided forth again deprived of all its nutritious properties. At present the river is eating somewhere else, perhaps in quite the contrary direction, and may reasonably be expected not to return here for many a day. Meanwhile the low and level sands are put to such uses as they will bear. Their first fruit is a spontaneous growth of tamarisk; a kindly shrub which clothes the bare waste with grace, and gladdens the traveller's eye with green, and his memory with the songs of a happier clime. It was in a tamarisk thicket that Ulysses captured Dolon, by Scamander bank; and the "humble tamarisk" gave the shade under which the Sicilian muses, and those not less sweet of later Italy, tuned the pastoral reed to sing the indolent charm of summer days, dreamed through in company with beauty and love. Not of these things does the Indian herdboy dream, as he drives his ungainly buffaloes through the clustering bushes of their new pasture-ground. The land is used in common by all the villages among which it lies; and, for a time, no one is careful to claim possession of any part of that which is of so small value. But the tamarisk roots bind the shifting soil; the droppings of their branches slowly fertilize the ground; the very cattle tread it into consistency, and enrich it after their fashion. Gradually the agricultural capabilities of the soil are restored; the useful jungle, having done its work, disappears in firewood, and ploughed fields begin to take its place. Patches of the richest soil are discovered here and there. The river has not wholly destroyed what it devoured, but has sometimes cast it forth little changed, covered perhaps with a thin layer of sand, but charged with the water which it wanted before. Luxuriant under-growth of clover attests the productiveness of the damp soil beneath; and when it comes under the hand of the husbandman, thick vetches and peas, and tall lush wheat, prove that the new acquisition is one which, save only floods, will yield the wealthiest crops in places now, and may be trusted to do so almost everywhere hereafter.

From this moment, the neighbourly joint occupation of the alluvial tract is at an end. Each of the surrounding villages asserts its undoubted claim to the whole. Perhaps a nominal settlement has already been made with some of them, while the land was yet valueless, and when nobody was minded to dispute a claim which did not immediately affect the rights of others. Now, however, that the value of the land has become evident, the nominal owner meets with all kinds of difficulties in enforcing his title. Whole fields lose their crops mysteriously in the night, the tenants are made to understand that they had better not try to enter into possession of the fields leased to them; and the land is openly encroached upon in all directions. It is in vain that orders, upholding the settlement are fulminated from the highest authority. Local influences are too powerful, local temptations are too strong. At last, after seven or eight years of continual lawsuits and criminal prosecutions, where victory inclines with glorious uncertainty to either side, the state of things is recognised as intolerable, and an English officer is sent out to put an end to it. This is indeed a great day for all persons concerned. For once, their conflicting aims are all the same,—to bamboozle the stranger who has come out to be an arbiter over them; only, of course, each wishes to mislead him in a different direction. Herein lies his safety, for the amazing discrepancy between their several stories soon suggests a wholesome doubt as to the truth of them all. If one were inclined to be serious, it would be difficult to imagine any more shocking moral spectacle than the utter disregard for truth displayed on all sides. The enquiry is one where a plain and fair statement is sorely needed. It is hopeless to try to unravel the tangled handiwork of the river, by inspection of the village maps drawn before the river took to transgressing it wonted bounds. Parts of the village lands, left undestroyed upon the high ground, can indeed be traced, but the moment one descends into the alluvial basin, all is delusion, nought is truth. Each claimant declares the lands of his own village to have occupied, if not the whole basin, at least the greater part it; and no piecing together of maps will enable the bewildered revenue officer to say with tolerable certainty where the old bounds of any one village really were. Only a professional surveyor, with the aid of the survey maps (which are other than the comparatively rude village maps maintained for revenue purposes), can restore the ancient limits, and give every one his due. The ultimate decision must of course be made by the revenue authorities. But one does not see why our magnificent survey maps should be left unutilised; nor why an annual survey should not be made of all alluvial villages, so as to keep up that which is most of all

wanted, and which would save immense vexation and trouble in the future—a timely record of all the changes wrought by the river.

JOTTINGS FROM MADRAS.

IT may not be uninteresting to your readers to hear how successfully the Famine Commission avoided the risk of being obliged to consider such facts regarding the agricultural condition of the Madras Presidency, as would have been given them, had the agricultural adviser of Government, Mr. Robertson's evidence been taken. Not only was his evidence not taken, but endeavours were apparently made to suppress, or not to bring to notice an elaborate series of answers to Mr. Elliot's questions, the issue of which preceded the formation of the Commission. The F. C. contented themselves with a morning's walk at the Sydapet Experimental Station, and with a cursory inspection of the temporary arrangements for conducting agricultural education there. Such a visit whilst it might seem to casual observers to indicate a wish to investigate the agricultural problem thoroughly, was in reality a mere blind, astutely devised by the Civilian guides of the Commission to prevent their unbiassed colleagues from hearing what independent observers consider to have been the results of the system of administering this country, for which the covenanted Civilians are primarily responsible. The Government of India were wise, in appointing Mr. Elliot to the position he occupies as personal conductor to the farce, which is now being committed. Not the slightest endeavour was really made to obtain the opinions, or to learn the views of the educated agriculturists in the service of the local Government. These facts would seem to indicate that the Supreme Government look with disfavour on endeavours to introduce a system of Rational Agriculture into this country; and that their Etcetera Department is only maintained for the collection of very incorrect statistics, which may be useful, but the object of which it is at present difficult to determine, and perhaps to furnish a number of comfortable berths for their protegees. If, instead of the present very unsatisfactory state of things which exists in Madras as elsewhere, the local Government would make full use of the establishment of agricultural officers, whom they entertain, much good work might be done. Not but that a great deal has already been performed, but all agricultural matters being under the direction of the Revenue Board, it is impossible to expect from that cumbrous and stop-the-way institution that any real endeavours will be made to give the country what it most requires. A similar arrangement, with regard to the Forest Department, was tried and found to fail most miserably. As was suggested by a writer in a recent pamphlet, the agricultural officers of Government should be taken from under the wet-blanket influence of their present superiors, and put in direct communication with the Government. It might then be easy for them to bring matters before Government without loss of time.

It was suggested in a local paper sometime ago, that Government should divide the Presidency into Commissionerships; if this were done, every Commissioner ought to have an agricultural adviser, who might also supervise the work of agricultural education in the local schools, on a system something similar to that prepared by Sir R. Temple in Bombay. Besides these local advisers, the Government ought to have on their staff some educated agriculturist to direct the operations they decide on, and to advise, on topics relating to his profession. Such an officer would find more than sufficient work in carrying out his duty. To him also should be committed the supervision in particular, of the higher educational work, such as that conducted in the agricultural college at Sydapet, and the general supervision, similarly to the Conservator of Forests in his own department, of all the agricultural officers of Government. It was suggested, I believe, to make 5 Commissionerships; if so on the plan which I now suggest, it would require the services of 7 officers to carry on such a work, besides trained native subordinates; thus—

Agricultural Adviser to Government, and Director of Agricultural Education	1
Professor of Agriculture in Central College	1
Agricultural Advisers to Commissioners	5
Total ..	

Such a system might be applied to every province of India, and would, I think, form an efficient ground work for starting substatial agricultural improvements. Of course it would be costly, and at present, in the face of late famines, and present war, might not be adaptable *in toto*; but nevertheless, with £1,500,000 to be spent per annum in measures calculated to lessen the effects of deficient rainfall, it should be possible for the Imperial Government to do something towards what most thinking men in India are beginning to look upon as the best means of averting future disaster.

What the intentions of the local Government may be I am unaware; but I believe that under pressure from Calcutta, in order to prevent Lord Cranbrook's surplus dwindling into a deficit, it is likely that considerable reductions in the public service will be made. If this be so, it is to be feared that in their present state of callous indifference to the real wants of the country, the Madras Government may show itself to be as benighted as its brethren in the other presidencies. It is however a good sign to see, that the native community is itself beginning to demand that their English rulers should not keep back from them the discoveries, which science has made, and which are so valuable to the cultivators, be he Hindu, or English, Parsee or German. Their demands are far more likely to be heeded than the warnings of any number of educated farmers.

MADRAS, 14th February 1879. AGRICOLA.

VILLAGE STATISTICS.

A NEW statistical register has been opened by orders of the Director of Agriculture and Commerce in the North-Western Provinces. It is an English list of villages, to be kept partly by native agency and partly by Assistant Collectors for the portions of districts under their charge. The object is laudable, and we sincerely hope it may be found capable of realisation. But we cannot forget that schemes, instituted on the first creation of the Director's office, four years ago, still remain in great part unaccomplished. The remodelling of village returns, in the vernacular, though long ago perfected on paper, has not yet properly begun to take a practical shape. There can be no question of the wisdom of the scheme; and it is, therefore, all the more provoking to find it frustrated by obstacles of a purely mechanical character, which demand only a little methodical energy for their removal. In some districts, matters are at a standstill for want of the new printed forms, which are not supplied till months after they are due. This is obviously a difficulty which ought never to have arisen. It is a gratuitous complication of an enterprise which has already to contend with a variety of embarrassments, due to the stupidity or untrustworthiness of the village accountants whose papers form the basis of the whole system. In this department, as in many others, the great desideratum is trained officials in the lower grades; and a special element of difficulty exists in the fact that the Government is not free to select these men with a single eye to their acquired qualifications. The wishes of the landowners must be consulted, and hereditary claims have to be taken into consideration. It is hopeless to expect good work from a village accountant who is on bad terms with the landlord; and if local rights be set aside, the family of the man passed over are pretty sure to make the village too hot for his rival. There are provisions requiring the examination of all new men, but they too often remain a dead letter. Organisation is wanted, and can be attained only by degrees. Meanwhile there is always a certain proportion of village accountants who are incompetent by reason of laziness or ignorance, or a fraudulent turn of mind. Their papers are constantly overdue, and when they do come in, they are found to be incorrect. Yet it is often found that the lesser of two evils is to retain these men in office, under a regular system of fining, rather than get rid of them on the chance of being able to supply their place with better. In fact, it is only on rare occasions that the quality of their work is brought under the notice of the Collector. One of the chief merits of the new statistical register will be an increase in the number of these occasions, and a more regular supervision on the part of the English officer. The register is to come into use next year; but one would be over hopeful to expect that it will be in full working order for two or three years to come.

Its principal claim to notice, however, is a matter of detail, unconnected with the general scope of the system it is intended to serve. We mean the little proviso that the figures, in the portion to be filled in by native agency, shall be recorded in Roman characters. We should be glad to welcome this simple rule as the herald of a great change. But if we look only to the immediate purpose of the register, we shall find reason enough to applaud the wisdom of so bold a divergence, albeit in a small matter, from the time-honoured practice of Indian scribes. In nothing is the perversity of Eastern notions more strikingly illustrated than in the fashion of recording numbers, not by plain figures, but by a kind of short-hand which takes up more room, is longer in writing, and is usually more or less capable of an interpretation to suit the reader's pleasure. The sole merit of this kind of notation is the symmetrical beauty of its appearance. A tabular statement filled up thus is a really pretty specimen of penmanship; but all regard for its neatness vanishes when the native clerk begins to read it aloud. The leading numbers are managed with comparative fluency, though mistakes occasionally occur even in these; but fractions of a rupee are invariably the subject of large guess-work and copious error. It is hardly necessary to remark that fractions are recorded in a fashion which, among Western nations, is peculiar to mariners alone. They heave the lead and read their soundings on exactly the same plan as the native accountant who records his small change in fractions of a rupee, not in units of annas and pies. The plan is a scientific one, and the record of it, as noted above, is calligraphic in a high degree; but for practical purposes the whole system is inconvenient and uncertain; and it has survived to this day only because all things old are treated with a semi-oriental reverence—wise enough, if not exaggerated—by the English rulers of India. We may perhaps hope that reform, once started, will take a wider range, and that not this single register only, but vernacular returns generally, will gradually come to be recorded in familiar figures. The change is one which might be made at once in all tabular statements compiled in the sub-divisional offices of districts, thus relieving the Central English offices, already overworked, of all the labour of translation. We cannot yet demand that the village accountants should keep their books on the same principle; but a beginning might be made by encouraging them to expect better chances of promotion if they qualify themselves to use English headings and figures to returns with which they have long been perfectly familiar. For the rest, there would be no such necessity of change. The names of the tenants, if written with tolerable care, are always fairly legible; and the adoption of the plan proposed—a perfectly feasible one, if worked with discretion—would render the village records intelligible to every Assistant Collector, without the need of any interpreting medium. It is superfluous to point out the great stride thus made in the direction of an effectual system of supervision. Familiarity with village records would be a simple matter, if the sub-divisional officer were able to carry them home and inspect them for himself, over his camp fire. This will never be done while the present vernacular method is in practice. No English officer has time to make himself thoroughly conversant with native handwriting, and it certainly is not desirable that he should create leisure for the purpose, by neglecting other duties for the sake of a mere mechanic art.

So much for the immediate effect of the new register, with its characteristic Roman notation. It is impossible, however, to resist the temptation to look beyond the domain of figures, and to speculate on the possibility of a widely extended use of English as the medium of official correspondence. The disadvantages of the existing system are so obvious as scarcely to need enumeration; but it may be worth while to remind the reader that nine-tenths of official correspondence in India is carried on in writing which the corresponding officers are unable to read; that the state of vernacular files depends mainly upon the interest or inclination of some native subordinate; that petitions are not perused but only listened to; and that mistakes are perpetually occurring because the listener's attention is otherwise engaged, or because the reader blunders in his monotonous occupation. One-half of the toil accompanying the charge of a district—and those who have tried it know what it means—is due to the single circumstance that the Collector is not free to take up files for himself, examine them, and write his orders with his own hand. No doubt, such a change would be a great one, and not to be made in a year, nor in several years, but surely it is high time to prepare the way for it. Nobody can suppose that the vernacular languages, with their manifold imperfections of vocabulary, structure, and utterance, will permanently continue as the medium of official or intellectual intercourse. But it is a mere want of foresight to neglect the preparation for a change which will certainly become inevitable. Already we have examples of a successful beginning in some isolated departments. No vernacular correspondence is permitted in the local Secretariats. It is not so long since the High Court of Allahabad decreed that all pleadings before it should be in English. Objections were not wanting at the time; but the result has been a vast gain to the public, both as regards appreciation of the points of their cases, and also in the expedition of business. The same high tribunal wisely determined that the Recorders of the Judge's Courts should in all districts be men conversant with English. The innovation was strenuously opposed; but it has amply justified itself by its results, proving that it rests only with the Government to create a demand, and the supply of English-speaking native officials will be forthcoming at once. Let the Government then extend its demand a little further. We do not advocate sudden or sweeping changes. A good beginning might be made with a rule requiring the head vernacular clerks of Commissioners' offices to know English, and providing that, after a certain date, these offices will decline to receive any papers in the vernacular. The next step would be a similar rule regarding native sub-divisional officers, as well as the central sub-divisional supervisors of village accountants. This much having been effected, the rest would follow of itself, while the immediate result would be an immense simplification of administrative work. Then the Collector could really judge the work of his sub-divisional subordinates, from reports and replies submitted in English for his own perusal, not interpreted by the tedious voice of a drowsy clerk, amid a dozen other distractions. The thing is quite possible. Here, as elsewhere, the French proverb holds good: It is only the first step which is formidable.

EDITORIAL NOTES.

OUR anticipation regarding the inefficiency of the fumes of burning sulphur (sulphurous acid gas), as a substitute for powdered sulphur, for the prevention of coffee leaf disease has been supported by actual experiment. Mr. Morris worked out a series of experiments with Mr. Wall's fumigating process, and found that the filaments and spores of the *Hemileia* were very little injured and recovered rapidly their vitality, after applying fumes which almost destroyed the foliage of the trees, which bears out what we said in our previous issue, *viz.*, that the sulphurous acid in its *nascent* state, is the most efficient means of destroying the vitality of the fungus.

THE annual Grant-in-aid of Rs. 1,200 to the Nagpore Agri-Horticultural Society, which the Government has contributed during the last five years, will probably be discontinued as the Chief Commissioner is of opinion that the results attained during the past five years are scarcely such, as to justify the Imperial subsidy now granted to the Society; and he thinks the Society will have no just grounds for complaint if the subsidy is withdrawn. The Chief Commissioner intends, however, to sustain the Society by such moderate grants as might to him seem necessary, from provincial funds. The Government Grant-in-aid, if withdrawn from the Society, might well be devoted towards the better carrying out of the objects of the Nagpore Experimental Farm.

A REPORT on certain crop experiments made in some districts of the Bombay Presidency during 1875-76, was forwarded to the Secretary of State in December last. In Dharwar and Canara, the

result of the experiments seem to show that the assessments on the lands in question is light compared with the gross value of the crops, the highest proportion being 6·8 per cent. in Dharwar, and 6·7 in Canara, above Ghats. In the absence, however, of information as to the probable cost of cultivation, these particulars do not show what proportion the assessment bears to the net yield of the land, which seems to be the most important fact to be ascertained: further, one year's experiments cannot produce any reliable data from which to deduce the general incidence of assessment to the yield of the land. In order to ascertain this, it is recommended by the Secretary of State that experiments should be continued annually in the same localities and under different conditions of of season.

AGRICULTURAL prospects in the Punjab are so bad that the local Government have considerad it necessary to call on all district officers to furnish early and full information on the following points:—*Ist*, prospects of standing crops; 2nd, stocks; 3rd, what works of most public utility they would recommend being started as relief-works.

THE condition of the people in Kattywar is causing considerable anxiety in Western India. Grain is almost unprocurable, or can only be bought at prices beyond the reach of the poorer classes. The formation of local relief works is being urged by the local papers to prevent the people from wandering into other districts, where they are likely to perish of starvation. A correspondent writes from Rajkote, the chief civil station of Kattywar:

"We must do something to save the cultivators who are the bone and sinew of the country, from the ruin and starvation, when they have pledged their last gold and silver bangle to raise money to feed their children. The post cart from Rajkote daily takes away the valuables and ornaments of the poor people to be sold in the Bombay markets. When they are reduced to their last rupee, the want and desolation of this district will be complete."

Two proposals for the construction of railways through the country have been under consideration for sometime. It is understood that the proposals have been approved of by the Bombay Government. No time should, therefore, be lost in providing employment for the bands of starving people who are wandering about the country.

A SMALL herd of Mysore cattle, the Amrut mahal breed, is to be sent to the districts of the Nilgiris, Coimbatore and Salem, as an experiment, to decide whether the cattle will thrive in the climate and on the natural herbage of these districts.

WE observe that the Government of Madras has given instructions that no applications for forest or shola land should be entertained on the Nilgiris until the whole district has been reported on, and the general question of land reservation, whether forest or grass land, has been considered and decided. Any such applications addressed to the Commissioner will be registered for future disposal.

FROM papers placed at our disposal, bearing on the introduction of the carob tree, we observe, that the Commissioner in Sind has distributed the carob seed among the Collectors of Kurrachee, Hyderabad, and Shikarpur, and the Conservator of Forests in Sind, with the following results:—

In the Kurrachee district the seed was sown in several places in the Jhemek, Shahbandar, and Sehwun divisions. In the latter alone the seed germinated successfully, but owing to the floods and heavy rain the seedlings were destroyed from submersion. In the Hyderabad district the experiment was tried at Salaru—the growth of the seedlings is described to be very slow, none being above 9 inches in height, but there are 180 plants in a healthy condition fit for transplanting. Besides the above some seedlings have been distributed. There is one plant already in the garden the growth of 7 years. It is 10 feet high and is not only healthy but it is stated to have made more progress this year than in any former year. In the Shikarpur district the failure was complete. The Conservator of Forests tried the experiment in the Sukkur, Nanabahra, Hyderabad, and Jerruck divisions. The result may be pronounced a failure except at Sukkur, where the surviving plants of which there are 25 out of 60 have attained the height of 5 ft. 6 in. and are thriving.

THE annual administration report of the Bombay Cotton [illegible] 1877-78 shows that during the year there was a considerable falling off in the area sown with cotton. In the northern districts of the Presidency, the rainfall at the commencement of the season was too scanty to admit of an extensive cultivation, and there was consequently a great diminution in the area sown, especially in the native States, while in Sind, owing to a deficiency of water in the Nara, and the late retention of the flood water in Thar and Parkar, there was also a decrease. In the southern districts, the rainfall was seasonable, and a greater extent of land was devoted to cotton there than in the previous year. The total area under cotton was 2,812,651 acres, or 410,586 acres less than in 1876-77. There was a net decrease of 468,428 acres in the area sown with indigenous cotton, and an increase of 57,842 acres in the cultivation of the exotic variety. The total quantity of cotton exported from the Presidency was 763,313 bales, of an estimated value of Rs. 7,28,05,307, showing a decrease of 216,514 in bales, and of Rs. 1,82,54,836 in value, as compared with the exports of 1876-77, which latter were, however, exceptionally low.

THE Chief Commissioner of Mysore and Coorg has sent Mr. Harman, Superintendent of the Bangalore Experimental Farm, on a tour through the coffee districts, to enquire into the causes of leaf-disease, and generally into the present state of coffee cultivation in Coorg. Mr. Harman appears to be going into his work heart and soul, and we have every confidence that his tour will benefit the planting community. We observe, Mr. Harman has been delivering some lectures in the Coorg Planters' Association Rooms before a considerable and appreciative audience, and has drawn *inter alias*, attention to the necessity of adopting a more rational principle of manuring, instead of the present happy-go-lucky style.

MAJOR NUTT'S agricultural fair and horse show at Songarh in Kattywar, a report of which appears elsewhere, appears to have been a great success. This is the first occasion upon which a fair of the kind was ever held in these parts, and the gathering is considered to have been very good. The Chiefs of Bhownuggur and Palitana were both present, the former presenting the prizes on the last day. The most important feature in the meeting was a course of lectures delivered by Major Nutt on agriculture. A course of study at the Agricultural College at Cirencester has made this officer quite proficient in this subject, and the zeal which has prompted him to impart his knowledge to the kunbees in such an out-of-the-way place as Songarh, is most praiseworthy indeed. Major Nutt's stay in Songarh has been a very short one, yet the improvements he has already effected in the place, as reported to us, have been very great. He has now been ordered to Baroda, and the regret expressed at his leaving Kattywar is very general. He will, however, have a large field for improvements open to him in the Gaekwar's territory.

WITH reference to the supposed discovery of the olive tree in Burmah, a correspondent sends a Ceylon contemporary the following note.—In the Forest Flora of Burmah by Kurz, four species of Olea, the genus to which the European Olive belongs, are given as natives of Burmah, *viz.*: 1. Olea dentata, Wall; with fruits the size of a small pea. 2. O. dioica, Rox. with fruits the size of a large pea. 3. O. terniflora, *viz.*, with fruits ovoid-oblong, nearly half an inch long, smooth, bluish black; and 4. O. robusta, Kurz, with small bluish black fruits, this last being equal to the Ligustrum robustum of Ceylon, where we have also the Olea glandulifera, Wal., and O. gardneri, Thw.. But it is evident from the size, &c., of the fruits of the Burmese olives, that none of them can be confounded with the European olive, and judging from the paragraph quoted, the discovery of a large edible or oil-yielding olive tree in Burmah, must be a species of mare's nest, and also that the discoverer, though he may have a vague idea of what an olive should be, is no botanist. Our Ceylon Weralus, from which Weralugstonna, in Ambagamuwa, pickled and sold in Colombo, or in their natural state in the bazaars, are very much like olives, and hence their botanical name *Elæocarpus*, but here their affinity ceases. They belong to a widely separated family of plants and the pulp of the Weralu does not contain oil.

MR. BADEN POWELL, Conservator of the Punjab Forests, has written an interesting pamphlet on some remarkable geological phenomena, known as the "chôs" or sand torrents of Hoshiarpore. The [illegible]

"chôs," induced Mr. Powell to direct his attention to the subject with the view of devising some means of checking their progress. "In one tahsil alone they calculate 35,000 acres of land covered with sand by "chôs"; it should not be forgotten that in this rich and well-peopled district, this land alone, if reclaimed, might be on our rent rolls, bringing in a yearly revenue of at least Rs. 50,000." In many other districts the same feature is noticeable. Immense quantities of ground, which, a few years ago, was under cultivation, have been devastated by these "chôs" to an almost incredible extent. The sand descends from the Hoshiarpore hills in streams which spread out in the shape of a fan as they descend to the plains. The "chôs" have even descended far down into the Jullundhur district, carrying destruction in their train. Mr. Powell gives the following description of the manner in which the masses of sand which descend in these torrents are supplied. "In the first place, the general surface of the hills is cut away, resulting in the abrupt and scarped appearance so well seen on crossing the Sutlej from Rupar. The *débris* of this is either accumulated in secondary ridges, so often observed at a short distance from the main range, or is absorbed into the current of a gradually-formed water-course. The rain-water as it flows towards the main lines of "chô" drainage is thus already charged with fine sand and mud, carried off from the surface abrasion of the hills, and thus it is already prepared to furnish a considerable amount of depositable material to the "chô." But the bulk of the supply is furnished by the giving way of the scarped surfaces of sand strata, which have been cut through by the stream, and now form its confining walls."

Mr. Powell proposes to deal with the matter by planting and artificial excavations, which will check the onward progress of the "chôs." He recommends Government to send "a trained Forest Officer to Hoshiarpore to act as Assistant to the Deputy Commissioner I would suggest that the Home authorities might be asked to select one of those now studying who has a taste for this branch of work, and let him have special opportunities of visiting such works as the reboisement near Embrum, which successfully extinguished the torrent of St. Marthe, the reboisement of the Luberon in the Department des Hautes Alpes, that of Karst in Illyria, and other such works." In course of time, some of the land may be reclaimed, and we shall no longer be presented with the picture of "mile after mile of the district cut up with the broad dry beds of sand, not only useless, but spreading their desolation further and further with every hot wind and every flood."

A RECENT number of the *Gazette of India* contains a mass of correspondence regarding the tussur silkworm. Some three or four years ago, the Government of India took up the question of "the possible development of a profitable industry in the silk of the undomesticated silk-spinning worms of India." The experiment has not been very successful, as regards either the quantity or quality of the silk. It has been brought to the notice of European manufacturers, but there appears to be little or no demand for it. The largest order received is from M. David, a silk manufacturer at St. Etienne for 2,000 kilogrammes of cocoons, "for the purpose of making experiments with the silk at his own cost." He offered to purchase them at one franc per kilogramme, but the Government could not afford to sell them at less than three or four times that amount.

In his letter giving this order, M. David asks the following questions :—

1st.—What is the chemical agent made use of by the natives to soften the cocoon and make it ready for reeling?

2nd.—Can the natives reel a cocoon more than a year old?

3rd.—What is the length of time elapsing from the making of the cocoon and the time of the coming out of the moth: does not that time vary greatly?

4th.—The cocoons in the bales are mixed in colour, dark and light: are these different varieties, and are they found on the same spots? Would it be possible to get only light-coloured ones?

The Resolution under notice requests the Lieutenant-Governor of Bengal, the Chief Commissioner of the Central Provinces, and other officials to furnish replies to these, and to other questions of a similar nature from M. Rondot, together with any other information obtainable on the subject.

WE make no apology to our readers, for publishing the following interesting extracts from a letter on the Nagpore model farm, from Mr. J. W. Neill, C.S., Commissioner, Nagpore Division, to the Secretary to the Chief Commissioner, Central Provinces :—

"I would say that while every argument which was used to demonstrate the utility of model farms in different parts of India, and amongst others at Nagpore remains unimpaired in force, there are additional reasons for maintaining a farm which has been established, for which land has been acquired, on which buildings have been erected, and to which a water channel to permit of the irrigation of part of the land has been made. In this case too the land that was taken up was naturally poor in quality, it had further been impoverished, the surface was uneven and considerably broken up, the rain water making channels for itself through many fields which sloped northwards. During the past 5 years much labour has been expended in levelling some of the fields, in deep ploughing all, in manuring a portion of the farm. It is only during the last two years that irrigation has been possible. The land has now very much improved, as was clearly evidenced by the rent of some fields let out to cultivators under circumstances explained in the half-yearly report on the farm submitted at the end of last month ; more remains to be done. All the fields are not yet in the best possible condition, and experiments on the farm have not been uniformly successful, but a fair amount of success has been achieved. Crops, unprecedentedly large in these parts of wheat and cotton have been taken off the farm, and the benefit of deep ploughing and careful cultivation has been acknowledged by surrounding agriculturists, although they have not yet taken to imitate what they admit to be good. That the example of the farm has not yet modified native practice, cannot well be construed into an argument that the farm has failed in its object. It has been established for barely five years, too short a time to effect much, even if the farm at starting had been in thorough order, the soil good, and fit for growing any kind of crops. In reality, however, the soil over a considerable part of the farm was at first incapable of supporting any but the poorest plant life.

I am disposed then to think that, if model farms in India are useful institutions, the Model Farm at Nagpore can claim a longer trial There has not been sufficient time to judge of it as an experiment. It no doubt is an expense, it costs Government about Rs. 500 a month net, but model farms are educational institutions. They do not yield direct returns, and it is in the hope of the indirect return that they are maintained. I would in conclusion express an opinion that if the farm is to be a success, the superintendent should be a man who can devote his whole time and attention to it, who has had some previous training, and has a knowledge of agricultural chemistry; and that he should be kept at his post for 5 or 6 consecutive years. If such a person were appointed, it might be possible to dispense with the native Superintendent, and in that way funds might be provided to make up the salary which would have to be given. It may be difficult, however, to find a properly qualified person, especially in India ; an ordinary gardener from England would be of no use, a young man would, I think, be required, one whose mind would be thoroughly open to new impressions, perphaps a young man who had passed through the course at Cirencester College might be secured in the first instance, and by the time his engagement expired, the agricultural colleges of Calcutta, Madras and Bombay may have trained natives and fitted them for such charges. The great difficulty is certainly in finding a good superintendent. Occasionally an officer in the Commission may be found qualified to manage the farm, but one cannot always count on that, and there is the chance that he may have to be transferred ; and the frequent change of superintendents is, I think, of all things the most to be deprecated."

We heartily concur in what Mr. Neill says, and are glad to see that the Chief Commissioner is likewise in favour of keeping the farm up, and intends placing the same in the hands of an Assistant Conservator of forests. The importation of Kew gardeners as managers of these experimental farms has, on the whole, not been successful. A proper use of the advertising columns of newspaper would, we are of opinion, result in procuring for these farms some good men, practical agriculturists, who are acquainted with native agriculture and its wants.

FURTHER experiments with the juice of the *Carica papaya*, or melon tree, have been carried out by Dr. Wittmack, of Berlin, which tend to confirm his provisional report on its energetic action as a solvent and ferment in contact with flesh or albuminous bodies. The results of his later researches may be thus summarized :—1. The juice of the *Carica papaya* is, or contains, a ferment which acts with extraordinary energy on nitrogenous bodies, and also effects the coagulation of milk in the same manner as pepsine. 2. It is distinguished from pepsine in that it acts without the addition of any free acid, and also at higher temperatures (60-65 deg. C.), and in a much shorter time. 3. Chemically the filtered juice differs from pepsine by yielding a precipitate on boiling, or on the addition of oxide of mercury, iodine, or any of the stronger mineral acids. 4. It resembles pepsine, as it occurs in the gastric juice, in being precipitated by neutral oxide of silver, or sulphate of silver, and in giving no precipitate with ferrocyanide of potassium, sulphate of copper, and chloride of iron. The *Carica papaya* being widely distributed in tropical countries, the collection of large quantities of the juice should offer no considerable difficulties, and Dr. Wittmack considers the attempt to be well worth undertaking, as this could be most advantageously employed in making meat, game, &c., tender in a short time (a point of much practical importance in hot weather), and also in dairy operations.

MR. MECHI of Tiptree writes :—" Have we forgotten Liebig? That giant of mental capacity, whose discoveries, and the theories deduced from them, have formed an imperishable basis for all agriculture everywhere and in all times. How puny and second-rate must appear, to any one who read and appreciated that great man's works, the simple practical illustrations and confirmations of his theories and dictum ; and yet these were for a long time disbelieved and opposed, but never confuted by proof of error. His mineral theory is riding now triumphant over error and prejudice, and we have at last learned the great lesson which he tried to teach us—that where are wanting in the soil the incombustible elements of plants in a suitable condition there can be no fertility of crop. Phosphate of lime and potash are now accepted as essential bases, while straw and chaff have gone to the winds, which contain the free ammonia that was for the first time only discovered there by Liebig. Is it not time—if not it never will be—when a monument shall record the immeasurable benefits which he has conferred on mankind! One rises from a profound study of his great works with a conviction that he has left little more to be done in the matter on the *Natural Laws of Husbandry*, the title of his last great work."

A ROOT show recently held in Berkshire has brought the sewage farming system forward under a somewhat more favourable aspect than has often been the case. There was, it appears, a section set apart exclusively for roots produced by this system of manuring ; and in all the five classes comprised in it the exhibits were, it is said, wonderfully fine. The first prizes all fell to the Reading farm, on which 110 tons of long red mangolds, 88 tons of golden tankard mangolds, 77 tons of yellow intermediate mangolds, and 77 tons of yellow globes were grown per acre. These are certainly very satisfactory figures ; and if sewage farming could often show such results, it would soon dispose of whatever financial difficulties have been experienced hitherto in connection with it. It ought, perhaps, to be observed that the crops exhibited were the first that have been raised on this farm, and the soil is described as 'new and fresh.' Under these circumstances exceptionally good yields were to be looked for, and perhaps would have been realized under any system securing plenty of manure. There is another alleged fact, however, which would at first sight seem to prove that no great allowance need be made for newness and freshness. On about fifty acres of the farm, it is reported, the same seed was sown, and the same culture adopted in every particular except that no sewage was applied. In this portion the crops yielded were less than half the weight of the rest. This seems to be a very conclusive test of the value of liquid manure. But it must be borne in mind that nobody has ever disputed its value, nor would any one be so foolish as to suppose that fifty acres of unmanured land could at all compete with other ground deluged from the sewers of a town. The only comparison worth anything is that between the and in a large number of cases, at least, it has been shown pretty conclusively that the difference in results is not satisfactory when cost has been taken into account. If the Reading farm and some others represented in the show referred to can maintain the crops with which they are accredited, no doubt they will be able to show very gratifying balance-sheets, and the inhabitants of Reading may be congratulated on their success in dealing with the troublesome question of sewage, even though it converts some of their neighbouring fields into spots that will be much the reverse of attractive in appearance.

AT last we appear to have something definite about the phylloxera, thanks to the International Committee, named at the Trocadero Congress, and presided over by M. Vimont. The Committee consisted of twenty-five members, six of whom where distinguished foreign vineyard proprietors ; they have examined the question from the first appearance of the malady in 1869, in the department of the Herault, down to the present moment : they noted the chief cures attempted—3,000 were sent to the Minister of Agriculture to claim the Governmental reward—and visited the suffering and the ruined vineyards. The report states the phylloxera was imported to Europe from America, and the disease can be propagated by artificial—transporting of plants—as well as by natural means—the wind chiefly. Stocks of American vines, as first revealed by M. Laliman of Bordeaux, can resist the bug ; they flourish vigorously when the native vines die ; the grafting does not in the least alter the delicate bouquet of the French grape ; but all American stocks are not equally resisting, the Solonis, Clinton Vialla, or Franklin, and Taylor being the best. The plant when attacked at the root, dies from inanition ; hence, any insect destroyer must be succeeded by a good manuring to give strength to the wounded plant ; after farm yard manure, the next best fertiliser is dried blood, with sulphates of potash and iron and superphosphates. The only efficacious insecticide is sulphuret of carbon, as first employed, on the appearance of the disease, by Baron Thenard, and abandoned owing to its severe effects. The manner of employing this remedy is now better understood : two injection holes per square yard, suffice to inundate the soil to the depth of 11 inches with the poisonous vapors, and some apply the quantity in 3 doses, at intervals of 4, 6, and 10 days. Submersing the vines drowns the bugs, but the flooding ought only to take place in autumn after all vegetation has ceased. Then the vines can support 11 inches of water, from 30 to 50 days, to be followed in spring by liberal manuring.

THE report of the Agricultural Department of the United States for the past year states that the maize crop exceeded that of 1877 by 30,000,000 bushels. The crop of oats is stated to have been the largest ever raised, and that of barley and rye was considerably in excess of that of 1877. The tobacco crop also showed improvement in quality. The averages of production as compared with 1877 are :—Kentucky, 60 ; Virginia, 73 ; Missouri, 56 ; Tennessee, 53 ; Ohio, 90 ; Maryland, 84 ; Indiana, 83 ; North Carolina, 89 ; Pennsylvania, 86 ; Illinois, 50 ; Connecticut, 86 ; Massachusetts, 95.—*British and Mercantile Gazette.*

A WRITER in an Australian paper states that in many districts of the colony the leaves of the celery are highly esteemed as food for milch cows, and are often preferred to red clover. The cows are said to eat them most greedily and to yield on this food a far sweeter and richer milk than on any other. Sometimes the leaves are cut up small, scalded with hot-water, and given as a mash mixed with bran and sometimes they are given whole in their natural state along with the other ordinary food.

THE experiments of Boussingault, Stohmann, &c., have demonstrated that, while the urine of carnivorous animals is rich in phosphoric acid, that of herbivorous animals has rarely any. Liebig accounted for the absence, by the alkalis of the urine being unable to dissolve the phosphates of lime and magnesia. At the University of Leipsic, some experiments were recently executed to call in question Liebig's explanation ; from which it follows, that when a herbivorous animal is submitted to its ordinary dietary, the liberated phosphoric acid is eliminated, not in

rich in alkalis, united with carbonic acid, which cannot dissolve the lime phosphates, and so allow its acid to pass off; but if phosphates of potassium be added to the forage, the phosphoric will be eliminated freely in the urine.

In India, Algeria, and certain parts of the southern provinces of Italy, the *Pelargonium rosatum* is grown upon an enormous scale, for the sake of an oil extractable from it very similar in odour to that of roses, and which constitutes an important article of commerce. This industry has of late been very injuriously affected by the adulteration of the genuine oil by the addition of liquid hydrocarbons, fixed oils, essence of copaiba, and similar substances, whereby its value in pharmacy, and for the preparations of perfumery, is greatly diminished. The *L'Italia Agricola* publishes the particulars of a simple test by which such adulteration may be readily detected. Five cubic centimetres of alcohol, of 70 deg. strength, are poured into a test-tube, six drops of the suspected essence added to it, and the whole well shaken. If the liquid remains clear it is a proof that the essence is pure, but the occurrence of the least turpidity indicates adulteration, owing to the fact that alcohol, of the strength named, will not completely dissolve the foreign substance or substances, and their presence in an undissolved state causes the turbid appearance of the liquid.

Some official papers received by a recent mail, describe the difficulties encountered in the suppression of the cultivation of the poppy in China. Notwithstanding fines and Imperial edicts against its growth and consumption, the result appears to be that more and more opium is produced and used each year. In some provinces very stringent measures are taken to suppress it, whilst others are overrun with the poppy, special dues being levied both on the land given to its cultivation and the drug produced. Then, again, the Chinese cultivators have discovered that the poppy is an exceedingly remunerative crop, and the local authorities seem to be not altogether indifferent to the fact either, for from the fines and bribes connected with the production it is believed that they reap a profitable harvest. In some respects, the higher authorities are powerless to act, for if they attempt to carry out the Imperial decrees, they are informed that to interfere with the crops will so impoverish the land-owners as to make the collection of the Imperial land-tax impossible.

M. Srupp, a German farmer, desiring to test the relative fattening qualities of rice and maize, tied up 18 bullocks in November 1877, in three lots of 7, 6, and 5 beasts respectively, and as nearly as possible under the same conditions as to age, weight, &c. The feeding was the same, save that the rations of grain, 6½lbs. daily, and in the form of flour, consisted of maize, oats, and rice. He found that 85lbs. of the latter exercised the same nutritive effect, as 100 of maize.

Messrs. Palmieri, Celi, and Grandeau have conducted experiments to test the effect of electricity on vegetation; they proved that in the case of maize and tobacco, the plants grown in full air developed with double the rapidity when exposed to the electrical conditions of the ordinary atmosphere. But it remained to determine effects in the flowering and maturing of the plants. M. Grandeau shows by his experiments, that the same rate of superiority, 50 per cent., was maintained, respecting the flowers and seeds of tobacco and maize, as was exhibited formerly in their growth.

For ages it has been known that solar light is indispensable to vegetation, and efforts have been several times attempted to secure the best conditions for plants exposed to solar action. The colours of plants have been modified, by moderating the intensity of the light to which they have been subjected; hence resulted the experiments, to determine what were the exact rays of light most directly beneficial to vegetation, as revealed by placing plants under glass of various colours. M. Paul Best has continued experiments on this subject, and while the problem is not exactly solved, he has demonstrated that they are the red rays which form the basis of the phenomena of vegetable life—transforming food, and building tissue; while the united rays that constitute white

A writer in the *Bulletin de la Société d' Acclimatation de Paris* record the results of a number of experiments with quinine sulphate on diseased silk-worms. A commission which reported on this subject in 1859 stated that silk worms treated with quinine or gentian never exhibited the same symptoms of cure observed in others which had taken either mustard or valerian; but Mr. Christan Le Doux, being in ignorance of this statement, has made further experiments, with satisfactory results. Worms suffering from *flackerie* were powdered with quinine, and nearly all recovered in a very short time after the application. Some very bad cases of *pebrine*, with open putrid wounds, were successfully treated in the same manner.

After finishing his Wynaad surveys, Mr. Brough Smyth is requested to proceed to Ootacamund and complete the investigation of the Nilgiri and Koondah Hills and their surroundings and then go to Canara and any other Madras districts which may be hereafter indicated. His services will then be at the disposal of the Government of India for the exploration of the Mysore gold fields. The illness of Mr. Withers and Mr. Thomas Laing has to some extent interrupted Mr. Smyth's labors. Mr. Laing is again unwell, and is not in a fit state to assist in the work which Mr. Smyth has in hand.

COMMUNICATED AND SELECTED.

THE ARGAN TREE OF MOROCCO.

The following extract from a report by Consul Drummond Hay on this tree has been placed at our disposal :—

"Considerable damage was done to the crops of 1877 by the locusts whose appearance in this part of the country was mentioned in my report for 1876, but as their devastating flight was limited only to a certain line of country, many provinces escaped the scourge. The prospects for the harvest of 1878 are at present very unsatisfactory.

Since the first rains in September only three inches of rain have fallen in Mogador and, it is reported, still less in Soos and the country lying between this port and Morocco. Cattle in the interior are starving for want of grass, and can be bought in the market for the value of their skins. In the neighbouring provinces of Haha and Spiedma the drought will be less felt as they are thickly wooded, and the forests of argan trees above all afford nourishment both for the natives and their flocks in times of scarcity.

This remarkable tree grows only in those provinces and Soos, and is utilised in the following ways. In the first place, the peasants extract an oil from the nut, which is useful both for burning and cooking purposes. When the nuts ripen and fall off the trees they are collected by the natives, who are aided in the harvest by their goats. These animals swallow the fruit for the rind, but, being unable to digest the nut, they throw it up again, and it is then added by their owners to the store for making the oil.

For their private consumption the peasants rarely make a large quantity of oil at a time, but crack open a few handfuls of nuts with a stone, and, after toasting the kernels in an earthenware dish, grind them into flour. The oil is extracted by adding water in small quantities to the flour, which is stirred in a bowl. As the oil is being formed by this process, the flour hardens into a cake, which is finally squeezed, leaving the oil perfectly clear and fit for use. This kind of oil-cake then serves as an excellent food for cattle, as also the dry rind of the nut, which is generally given to them with the cake, forming together their principal and most nutritious food during the year, and is invaluable to the natives in time of drought, for the argan tree is very hardy, and a dry year has little if any effect upon it.

Even the empty husk of the nut, when broken, is not thrown away by the peasants, but used as fuel. The best charcoal is made from the argan tree, and the dry timber is excellent firewood. The goats feed also upon the leaves of the tree, and when browsing in the argan forest may be seen climbing amongst the trees, plucking and nibbling the nuts and leaves.

MEMORANDUM BY DR. G. BIRDWOOD, C.S.I.

I had already made inquiries about the argan tree, and have learned from Professor T. Dyer that it is the *Argania sideroxylon* of botanists, one of the *sapotaceæ*, an order to which many well known Indian trees, both naturalized and indigenous, belong.

The indigenous species in Bombay are *chrysophyllum roxburghee* "turséphul;" *sapota tomentosa* "koombul"; *Isonandra caudolliana*, a tree of the same genus as the gutta percha tree; *Bassia latifolia*, the celebrated mowah, from the flours of which mowah spirit is distilled, and from the seeds of which a large quantity of oil is obtained, used for making soap in the Kaira zillah, and the wood of which is used for the naves of wheels; *Mimusops elengi*, "buckool"; and *mimusops hexandra*, "kurnee," the tough close grained wood of which is used for making sugar-mills.

The introduced species are *Chrysophyllum pomiforme* from Jamaica; *Mocarpus edulis* from Otaheite; *kunki* from the Moluccas, and *Achras sapota*, the sapota plum of South America, which has become thoroughly naturalised in Western India, and yields a fine dessert fruit, the size and shape of a quince, covered with a rich brown rough rind very sweet to the taste, and containing two or three large smooth chestnut coloured seeds yielding oil.

There is every likelihood, therefore, of the argan tree succeeding in India. In what localities it would succeed best it would be difficult to say beforehand, with any certainty. Morocco consists of the southern slopes of the Atlas range, which stretches in a curve from Cape Gher on the Atlantic to Cape Deir, opposite to Gibraltar, and falls from an elevation of 16,000 feet to the low lands in a succession of terraces exposed to the full influence of of the North-west wind laden with the moisture it has gathered for more than a thousand leagues in its way across the North Atlantic Ocean. The natural heat of the country lying so near the Tropic of Cancer is, therefore, tempered both by the rain-clouds, which hang over it from October to February, and during the spring and summer months by the south wind, which comes over the snow which lies perpetually on the summits of the minor range of the Atlas mountains, producing one of the most agreeable and fruitful climates in the world. The littoral vegetation is that of the Mediterranean generally. The olive, laurel, citron, almond, and fig, and the myrtle, cyprus, oleander, white poplar, and aloe, grow everywhere; while the minor uplands (slopes and valleys) are covered with dense forests of tropical trees. Taking these physical facts into consideration, and the cosmopolitan character of the order, and the fact that innumerable African plants, both Mediterranean and tropical, have become completely naturalized in India, it is probable that the argan tree also will flourish in India, everywhere but most in sub-alpine tracts exposed to the sea breeze and an annual rainfall of from 50 to 25 inches.

It would be most useful of course to encourage its growth in districts exposed to droughts.

It will be observed, however that it is very similar in its economic properties to the mowah tree and sapota plum. The mowah is one of the noblest native forest trees of India and is plentiful everywhere in Western India, at least in the Concans, on the Ghats, in Guzerat, and Rajwara, and if more of a tree like the argan is wanted in India, it would probably be more profitable to encourage the extended cultivation of the indigenous mowah, than to squander money and time in the attempt, which might after all prove vain to introduce a new and imperfectly known exotic.

GEORGE BIRDWOOD.

30th August 1878

Mogador, 1st November 1878.

Extract Despatch from Her Majesty's Consul at Mogador.

The season here for sowing the argan nut is during the winter months; it does not take longer to sprout than a melon seed. The tree is quite indigenous to this part of Morocco, growing only in the hilly districts lying south of the river Tensift (near to Suffee), and I am informed that all endeavours to cultivate the tree in any other part of the country have failed. The soil in which the tree thrives is composed chiefly of limestone and sand. It will grow in very rocky and strong ground, but I have noticed that the finest and most fruitful trees are those which grow in cultivated ground.

Samples of the oil cake and dry rind of the nut upon which cattle are fed might interest persons desirous of cultivating the tree, and I should have no difficulty in procuring and forwarding them if required.

A. DRUMMOND HAY.

REPORT BY DR. G. BIRDWOOD, C.S.I.

I have examined these seeds. They are in prime condition, and if forwarded to India forthwith by the out-going mail will arrive at the most favourable time for sowing them, at least in Bombay. They should be sent in the bag in which they have come, laid in a strong deal box. Copies of all the papers relating to them should be sent with them for the guidance of those to whom the rearing of the trees will be entrusted. I would venture also to suggest that they should be addressed to Bombay, from where they would be most conveniently distributed to the rest of ....

GEO. BIRDWOOD.

17th December 1878.

AGRICULTURAL MEETING AND CATTLE FAIR AT SONGAD, KATTYWAR.

THE following account of this gathering will be perused with interest:—

According to announcement the above assemblage of men and animals, together with a large collection of things, was held at Songad on the 13th, 14th and 15th February. The title chosen for the proceedings is too modest. It was really a good agricultural exhibition, though the first of its kind that has taken place in these regions. Major Nutt seems to have the enviable power not only of originating new things, but also of influencing large bodies of men and bringing them over to his own opinions; and he certainly is to be congratulated on the success of this enterprize, which owed its conception to his own brain and its accomplishment to his peculiar tact, energy, and administrative ability. It is pleasant also to know that his scheme was heartily seconded by liberal contributions of money and other forms of help from the neighbouring Chiefs, particularly those of Bhawnagar and Palitana, both of whom were present on the occasion and took a deep interest in the whole proceedings.

Songad is well situated for such an exhibition. It has an attractive and healthy situation, and is supplied with abundance of running and well water of the best quality. A capital macadamised road, branching out to Palitana, Rajkot, Bhownuggur, and Gogo, furnishes additional advantages for a large gathering of men and agricultural products. A large grove of mango trees skirting the banks of a pretty stream, afforded by its excellent shade an admirable camping ground and protection on this occasion for the long rows of horses, buffaloes, bullocks, and other animals which were tied under its branches. From the road a broad avenue, lined on each side with gay flags and devices, ran down to the encampment, and with its crowds of men and rows of busy shops had a most interesting and business-like appearance. The fair was altogether a new thing for Songad and will long be remembered and talked of by hundreds of families throughout a radius of 50 or 60 miles. Even Surat, across the gulf, was represented, and some of its enterprising Parsis exhibited first class specimens of fruit, vegetables, and grain. Such exhibitions must do a world of good in the improvement of agricultural products, the elevation of cattle-breeds, and the general international and political benefits arising from the free intercourse of different Chiefs and the competition of different States cannot but be of the most salutary character. The proceedings of the Exhibition were arranged as follows:—

FIRST DAY

At noon Major Nutt very appropriately inaugurated the business by a carefully prepared lecture on "Soils," delivered first in English and then in Gujarati, in a spacious tent, before an audience of nearly three hundred, including several Chiefs and a large number of other native gentlemen; and the earnest attention which was given to every sentence evidenced not merely the novelty of the subject, but the absorbing interest taken in it. It is questionable if five persons of the native audience had ever before dreamt that so much could be accurately known of the components of the soil they have been so long treading and trying to make profitable. The subject was divided into six sections—namely, the origin, the formation, the distribution, the physical properties and surrounding conditions, the classification, and the chemical composition of soils. The entire mineral matter of soils, the lecturer said, has been derived from the gradual decay of rocks, the process going on from age to age through unnumbered years, and being still in active operation. The process is caused by various agents, such as temperature, moisture, and the action of the atmosphere and vegetation. The first product of pulverised rock is lichens, then mosses and grass, then higher forms of vegetation as the moistened dust becomes more and more mixed with organic matter. The physical nature and productive powers of a soil depend on the proportion in which its constituent parts are blended; those constituent parts being sand, clay, lime, vegetable matter, and mineral fragments or stones. Hence it is the duty of the farmer to ascertain the elements of which his soil is composed and their proportion to one another and select his manure and his seed accordingly. To prove that his advice meant more than talk, Major Nutt volunteered to have all samples of soil sent to him for analysis thoroughly tested by a professional chemist, and brought an extremely useful lecture to a close by urging his agricultural hearers to turn over a new leaf by going deeper down and turning up the virgin soil that has lain undisturbed in almost every field in India since no one knows when, waiting only to be brought to the surface to prove its native strength by producing heavier and richer crops. This was much-needed counsel, for the native cultivator seems never to have heard the burden of the good old rhyme,

> Plough *deep* while sluggards sleep,
> And you'll have plenty of corn to sow and to reap,
> And plenty of money to spend and to keep.

The next part of the first day's work was the judging of grains, vegetable, and fruits. There was a very good show of these products, and many specimens were of a high character. Among grains it was noticeable that a Christian colony near Gogo had introduced several kinds into Kattywar, which had hitherto been unknown, except in the shops, and had introduced them most successfully. It was commonly believed that these sorts were not adapted to Kattywar soil. The fruit and vegetable stalls also showed marks of enterprise and advance in the form of foreign products, among which the potato, cabbage, tomato, turnip, salad, and English apple were conspicuous. The gardens of the Bhownuggur Darbar carried off most prizes but other States and private gardeners had also a share. Some of the fruit and vegetables, both native and foreign, were exceedingly fine.

Second Day.

The business of the second day opened with inspection of animals and deciding on their respective merits. The show of horses was exceptionally good, and well sustained the character of Kattywar as a breeding province. It comprised the celebrated pure Kathy horse "Reddo," the property of the Thakore of Bhownuggur, and the equally well-known "Anstey," a thorough-bred Arab of 15 hands in height, the property of the Thakore of Palitana. Both these horses were universally admired. It was a ticklish point, I am told, to decide which of the two should have the first prize, for they are both A 1 specimens of their respective classes. Ultimately it was agreed to place "Reddo" at the head of the list, rather in consideration of the meeting being especially for the improvement of the indigenous breed than for any superiority the Kathy had over his Arab compeer as first class animals.

Among the mares there were none of the country-bred of such excellence as to surpass the imported mares of the Thakore of Palitana, one of which, a high caste Arab, had been obtained by him direct from Arabia at great expense and by means of a good deal of tact and diplomacy with an Arab Chief. Horse-breeding is quite a passion with the Palitana Thakore, and he had good reason to feel proud at the exclamations of high approval which some of his home-bred stock drew forth. The Arab mare above mentioned is now in foal by "Anstey," so that the produce will be first class. There was a good show of "Reddo's" offspring, a very fair proportion of which secured prizes. They resemble their sire in all respects, except the hind quarters, which, in the opinion of some, lack proper development; but the Thakore of Bhownuggur must be congratulated on the point of perfection already attained by him in this most important matter of horse-breeding. He and the Thakore of Palitana had each about 30 horses for competition, and both gained several prizes. It is worthy of note, however, that neither of the Thakores took the prizes to which they were entitled, but generously left them to be distributed among private winners. This, together with the abundant supply of grass furnished to all exhibitors gratis, shows that these Chiefs take enlightened views of the duty of rulers, encouraging their subjects and advancing the interests of their States even at their own personal expense.

The show of buffaloes cannot be overlooked, for it embraced some remarkable samples of a breed of buffaloes hardly to be met with elsewhere than in Kattywar or Guzerat. These belonged to the Thakore of Bhownuggur. The main peculiarity of this breed is not so much the enormous size of their bodies or the quantity of milk they give (a maund a day), as a most singular formation of head and horns. A large mass of redundant flesh rests on the crown, extending down on both sides of the face like a huge hood, and, in some cases, almost completely covering the eyes. The horns, which are extraordinarily broad and thick, seem to grow out of the lower edges of the hood downwards and then turn up with a lateral twist towards the shoulder, forming sometimes almost a complete circle. A distinguished lady from London, Miss North, who is now making a sketching tour through India and who happened to be at Songad at the time, could not resist the temptation of having a "sitting" from these marvellous-looking brutes and in a very short time dashed off a splendid oil-painting of a group. So we may meet the Bhownuggur buffaloes again—perhaps even in the *Graphic*.

Bullocks elephants, camels, sheep, goats, donkeys and poultry, all had a place at the Exhibition and shared in the honour and benefit of prize-taking.

At 3 o'clock P. M., Major Nutt resumed his course of lectures, the subject this day being "Manures." The large increase in the audience at this lecture evidenced the high appreciation of the previous one. The enormous tent was almost completely filled, the numbers present being not less than 400 persons. The subject was treated under two heads, "General Manures" and "Special Manures." All manures being nothing more nor less than plant food, general manures are those which repair the entire loss sustained by the soil in the production of all kinds of plants, and, through them, of animal matter. Such manures bear a similar relation to soil products that milk, which is a general food of animals, bears to the animal body, *i. e.*, a tissue-builder. The best of these manures is cow-dung, which, it is to be regretted, is so largely used in this country as fuel. This is a most important consideration, and points to the great desirability of extra effort for the supply of wood or other species of fuel. Who can estimate the amount of loss to agriculture caused by this universal waste of the best manure which can be given to the soil? In this view of the matter, every man who plants a tree is not merely increasing the shade-comfort of his fellows, the supply of timber, and, according to current theories, of rain, but is also, though unconsciously, adding to the fertility of the soil by in so far diminishing the necessity of burning cow droppings. In the same way the introduction of coal, if possible, would tell powerfully on the agricultural products of the country. These are thoughts which are capable of large expansion and might perhaps even connect themselves with the all-absorbing famine question.

Special manures are those which repair only particular wastes from special crops, or supply particular defects in the soil itself. Liebig's well-known "Law of Minimum" was explained and urged on the consideration of the audience. The teaching of this law is that, as every field contains a maximum of one or several, and a minimum of one or several nutritive substances, and that it is by the minimum that crops are governed the way to obtain the best crops is, after ascertaining the elements of a given soil, to add to it such kind of manure as will supply the elements most defective. A large quantity of excellent manure may be put into a field, but owing to its richness in certain elements with which the soil is already charged, or its deficiency in certain elements in which the soil is already deficient, profitless expense and disappointment only are the result. Towards the close of the lecture Major Nutt referred to the very fertilising property of bones used as a manure, and entreated his audience not only to prevent the removal and exportation of bones from their villages which had now begun, but to carefully preserve and turn them into manure; and the lecture was closed with an experiment in making bone manure in the presence of the crowd. The simplicity of the process showed that any man of ordinary intelligence could easily make artificial manure for himself and that, too, at the trifling cost of a little sulphuric acid.

The most important proceeding of the day was a ploughing match. No less than 40 ploughs and pairs of bullocks stood at their posts waiting the first sound of the gong to start them to work, and immediately the sound was heard a most spirited competition began and was maintained for half an hour, the allotted time. Some of the ploughing was very good, but still the great defect of the native plough and system of ploughing were evident in almost every allotment. In one lot only were there marks of a decided improvement. This was ploughed with a light English plough adapted to India, and brought from the Christian colony already referred to. In this lot the furrows were deep and wide, and the soil thoroughly broken, turned completely over, and left exposed to the atmosphere. This plough was the admiration of all, and the desirability of generally adopting it was freely expressed by the crowds that gathered around and watched it at work. The same kind of plough has been in use for several years in another Christian colony near Ahmedabad where more than twenty are now employed, and where its superiority over the native instrument has been clearly established. A specimen of the English harrow from the Gogo colony also was exhibited and highly commended. The proceedings of this day were wound up in the evening by a moderate display of fireworks.

Third Day.

The work of the third and last day consisted in fresh experiments with the English plough and harrow, the delivery of the third lecture, the general parade of prize animals, and the distribution of prizes which was kindly undertaken by the Thakore of Bhownuggur. The third lecture was a practical summary of the preceding two with an explanation of the principles of the horse-breeding and illustrations of the advantages to be derived from it superadded. It may be suggested to Major Nutt that he might kindly allow these lectures, in their Guzerati dress at least, to be printed *in extenso* in some of the Vernacular papers. They would do more good to the country than a large amount of the matter which these journals are continually sending forth, and being in Guzerati, would be read by large numbers of natives.

It is to be earnestly hoped that this is only the first of a long series of such exhibitions in this part of Kattywar, rehearsed at intervals as short as possible, advocated by the press, and heartily aided by Political Agents and Native Chiefs.

THE CEREALS ON THE HIMALAYAS.

Memoranda on the Cultivation of Wheat and some other Food Grains in the Himalayas.

Grown at an average elevation of 6,400 feet, having a range of 1,000 below and above it. Situation, Koteghur, near Simla.

THE fields are situated at a distance from the villagers' cattle styes (*khood*) and therefore have been but seldom manured within the past thirty years, so that they are considerably reduced in their productive powers. They are on the N slope with the aspect (generally) W. by N. The soil is of a good thickness; chiefly argillaceous, overlying micaceous-schist rock; drainage perfect.

The fields were rented to the villagers on the usual local custom *adha per*, that is, on half shares; the land-owner obtains one-half of the crop, the cultivator the other half. Under this arrangement the land-owner lends the land, while the cultivator finds the seed and also provides all the labour and implements necessary for ploughing, sowing, reaping and threshing out, delivery being taken at the threshing-floor. It is necessary to add that the seed-grain is first of all deducted from the new crop (*Bithu*—Chenopodium sp. excepted) after which the division of the crop is made. Where the cultivators are very poor, the seed has been advanced to them without any interest.

Some local Weights and Measures.—The inhabitants reckon the seed required for and the outturn of their fields in *bhars* and *patis* (or *tatis*) the measures for the different crops not only vary in size, but also in weight, though the standard *bhar* may be taken to consist of 32 seers *pucka* (2½ lbs avoirdupois to the seer.) In all cases though 16 *patis* = 1 *bhar*.

The bhar measure for	Wheat, Indian Corn & Kolth	=	32	srs.	(80lbs. Av.)
" "	Barley, ...	... =	24	"	"
" "	Rice (*Keri* or coarse description)	=	25	"	"
" "	" (*Basmati* or table ")	=	21	"	"
20 pattis of	Wheat, Indian Corn and Kolth make		1	md.	"
27 "	Barley	... =	1	"	"
25½ "	Rice (*Keri* or coarse description)	.. =	1	"	"
30½ "	" (*Basmati* or table ")	... =	1	"	"

Note.—One part of basmati is reckoned equal to two parts of coarse rice.

A *mun weighs* 16 *seers* (32 lbs. avoirdupois): 2½ *mun* = 1 *maund* (80 lbs. avoirdupois.) The *mun* is also frequently designated "kucha maund." A *kucha seer* = 6¼ *pucka chittaks* (about 13½ avoirdupois) = 16 *kucha seers* = 1 *mun*. A *patti* is 2 seers in weight = 4 lbs. Avoirdupois.

								24	18							

From this book the items are transferred into the Field Ledger wherein each field has its own heading, and by means of which the rotation of crops, manuring, and other agricultural operations can be regularly recorded.

The villager's "J... " fields are much more productive (12-16 fold = 18-24 bushels* per acre) owing to their proximity to the cattle-styes, where they can be readily manured: These fields also yield two crops in the year, i. e., one crop of cereals, and one crop of millet, peas, &c.

Sundry Notes.—It is not advisable to manure the land before sowing the seed as it produces too rapid a growth, weakening the straw, (known by the term "running to straw") and increasing its quantity at the expense of the ear, which does not attain its proper development. The best time for manuring is just before the December rain falls as it is then well washed into and mixed with the soil.

The wheat is ripe when the straw is dry and yellow below ear, if then cut the largest yield of flour is obtained.

The difference in colour between the red and white wheats is owing chiefly to the soil; the latter gradually becoming darker and ultimately red in some stiff wet soils; and the former lose their colour, becoming first yellow and then white on rich, light and mellow soils.

Some of the zemindars add to their incomes by lending out seed on 25 per cent. interest, i.e., for each maund of seed lent 1¼ maund is returned, at the succeeding harvest.

The outturn (Proportion to Self) is entered into a Grain Ledger (left handside), while on the right the issues or sales are entered, and from this book the money from the sales is passed into the Cash Book, ... of grain only takes placeon Saturday afternoons, at the same time that the labourers recieve their wages.

CALLOPHYLLUM INOPHYLLUM.

AMONG the successful experiments carried on by that most useful of local institutions—the Agri-Horticultural Society of British Burma—with seeds of useful economic plants, is that of raising in a small nursery a number of seedlings of the *Callophyllum Inophyllum*. The plants so raised were reported some time ago as being in a healthy condition promising well.

This species of the *Callophyllum* is a valuable oil-yielder, and a native of the East Indies. It was first brought to the notice of the botanical world in the year 1793; but in the East it has long been known and esteemed for the oil it yields. In Southern India this oil is known as *poonnay* or *poon*; in Orissa as *poonung*; and in Hindoostan as *sur-pun-ka-tel*. The genus comprises large growing timber trees, and the species *Inophyllum*, in addition to yielding the famous oil, gives a timber, which Dr. Balfour, quoting Mr. Dalrymple, says, is superior to the yield of nearly every other tree for the knees of ships, and as crooks in general. In some parts of India and Ceylon the wood is used for masts, and cross-sticks in native cargo and fishing boats, as well as for bullock-cart poles. A cubic foot of it weighs 40 lbs. It is thus lighter than teak; almost of the same weight as red pine, jackwood, and the Nassau species of mahogany; and heavier than larch, chesnut, fir and elm, though not the Canadian growth of the last. The graining of the wood is coarse; but the wood itself is very strong, durable and ornamental, and is used at times in ship-building in Madras.

Apart from its oil and timber, the tree is in great request both for its beautiful leaves and sweet-scented flowers. The former, in technical language, are described as opposite, simple, coriaceous, shining, close veined, entire; the latter (the flowers, as auxillary, drooping, in racemes, fragrant, white, polygamous. Such a description, however, will hardly afford the lay reader an adequate idea of either the beauty of the foliage or the sweetness of the flowers. It needs but a sight of the former to distinguish them ever aftewards, as they are unlike most leaves, oval in shape, of a dark shining green, quite leathery to the feel, and their veins run close to each other in clear, distinct, almost parallel, lines, while a well defined vein forms a margin all round. In Java they are grown principally for the shade they afford and the scent of their flowers. Here, in Burma, Dr. Mason tells us, that specimens might be seen in the vicinity of the native monasteries, and that they are remarkably handsome plants. Their easy rapid culture is no small recommendation. Seedlings, as a rule, are not transplanted, but put down in chosen sites and there the plants remain for the rest of their existence after sprouting. Writing from personal knowledge of this beautiful plant, we can state, that the seedlings are not injured by transplanting from the nursery to a locality selected for them; and some of the handsomest plants in the gardens of Calcutta have been so treated. The best plan, we have found answer, is to let the seeds drop from the branches on the soil underneath and germinate there, afterwards to transplant when the seedlings are a few inches high.

The plant loves the sea-breeze and thrives within the radius of its influence much better than anywhere else, no matter how favorable the locality in other respects. It delights in a rather sandy soil, and from this we are led to believe Rangoon and its vicinity will be found suited to its growth and culture. Indeed some plants here are quite as good as the best we have seen in India. As to methods of propagation, that from seed is to be preferred to cuttings, though these root freely in sand under a bell-glass.

Its notice here, however, is not for the purpose of advocating its adoption as a shade-giver, or garden ornament: it is from an economic stand-point that attention is drawn to it. The cultivation of the plant might with advantage become a local industry. Thus viewed, the oil is its most valuable yield, and the seeds are said by some to give sixty per cent. of their weight in oil. Castor, however, highly oleaginous as are its seeds, yields only about a third; and the produce from the *Callophyllum Inophyllum* may be set down at that mark too, especially as it is currently reported amongst natives, who do extract the oil, that this rate is usually obtained. The uses to which it is put are not many. It is used medicinally, but not culinarily; for lighting, but not for lubricating. It is never put into the cooking pot, nor is its cake given to cattle. But *khoberajes*, or native physicians, prescribe it for rheumatism, and the Indian dâk-runner saturates a bunch of leaves with it for a torch wherewith to scare away wild animals as he speeds on his jingling way through jungles and topes, carrying mail-bags. Medicinally its use is extremely doubtful, as the British Pharmacopœia is silent regarding it, and our druggists are ignorant about it. The chances are its efficacy in rheumatism is owing more to the friction employed in rubbing it in than to any inherent specific virtue. As sold in the bazaars of India and Burma, the oil is a crude substance, seldom if ever refined, and best suited to burning. As such, it ought to possess a value here where cocoanut and castor-oil are both so high-priced. In India—in the Hill States and in Calcutta,—a maund fetches Rs. 10; but some official papers regarding it state, that in Kyouk-Phyoo as much as Rs. 40 is obtained for the same weight. The use of the hydraulic press would, we fancy, procure a clearer, at least a better-looking produce in place of the dirty, greenish color, and the body instead of being opaque through impurities, would be limpid, just as "cold drawn" castor-oil. A few experiments might be tried in this direction.

Its timber is also another object for its extended cultivation. The local government has not neglected the matter, as we are informed experimental cultivation with it has been tried in some of our jails—Kyouk Phyoo particularly. But the local administration has ceased to publish papers of such nature in the Supplements to the *British Burma Gazette*, and it is hard to get departmental officers to communicate any thing. The Inspector-General of Prisons was written to the other day for a few particulars of the results of the experimental cultivation in jails, but the information was not supplied and reference was made to the Secretariat. Knowing that Mr. Burgess and his office are just now overwhelmed with work, we have not thought proper to trouble them; but Dr. Kelly might very well have obliged, as neither the welfare of provincial jails, nor that of the country at large, would have been jeopardized by the public being enlightened n the subject.

AGRICULTURAL EXPERIMENTS.

THIS is a great age of experiments. In all branches of knowledge inquiry is stimulated to the utmost. Nature is eagerly questioned and beseeched to unfold her secrets. Her ways and means of working are tested by the scientific experimentalist. Eager to learn, devoted to his work, he wrests from Nature slowly, and one by one, some precious truths that have long laid hidden and unsuspected by man. At first it may appear that the new truth is simply an abstract fact bearing no relationship to any phase of human labour and daily life. But it does not remain long before skilful mind and hand applies it to some practical use for the public good. Whether the discovery be a new light, one of the laws of sound, heat, or motion, it is soon made available for the interests of trade and commerce.

In all departments of art and manufacture there are vigorous, untiring explorers. Agriculture in the present day in particular has a host of devotees. During the last quarter of a century most important work has been done in scientific investigation of the properties of soils, the elements of plant life, and other subjects connected with the pursuit of agriculture. Our chemists have been indefatigable in their researches. They have sometimes erred in their deductions, and have had to submit to correction. For the most part they have worked honestly, their only object being to ascertain the truth and not to bolster up preconceived theories. The ordinary farmer also has acquired a taste for agricultural experiments, and no longer plods his weary way through life with an uninquiring mind as his ancestors did in days gone by. In England, on the Continent, and in America a host of explorers in scientific agriculture are found. The results of their experiments are always interesting, although not unfrequently inexplicable. A large number of experiments made lead to little practical good. This will always be the case, but they should not therefore be discouraged. Out of the multitude of counsel some wisdom may always be obtained. But the various conditions of soil, climate, aspect, character of the seed, and various other disturbing causes render the attainment of absolute scientific truth difficult in agriculture.

Agricultural experimental stations supported or subsidized by Government, common elsewhere, are unknown in England. Agricultural research is left to private individuals or to farmers' clubs, societies, or associations. Mr. J. B. Lawes is the greatest private experimentalist, not only in England, but in the world, and agriculture everywhere is indebted to him for his noble work. Dr. Voelcker, acknowledged by all to be the leading professional agricultural chemist amongst us, has enriched our store of knowledge with the results of years of laborious and original research conducted in the most conscientious and painstaking manner. Other labourers in the same field, less skilful, less original perhaps, have contributed to adorn the literature of agricultural chemistry in recent years. When to the labours of pure scientists we add the combined action of practical agriculturists, the stock of agricultural experiments on hand is large. Those of most importance are the Rothamsted and Woburn experiments. But in various parts of the kingdom investigations on a smaller scale of great interest and value are conducted. In Scotland especially there are several societies that have entered the field of independent inquiry—and with more or less success. But before any definite conclusion can be arrived at in the relation of special manures to special crops, trial must follow trial with a tedious pertinacity of effort. Hurried generalizations on the result of a few experiments only mislead farmers, and hinder the progress of scientific agriculture.

In judging of a single experiment there should always be considered the possibility of experimental error, or the influence of some exceptional unknown causes, especially when the result appears to be at direct variance with general experience. When, for instance, a crop of turnips is lighter where superphosphate is used than where it is not, some suspicion should be aroused, and no hasty conclusions should be made. In one instance we believe

in the Woburn experiments, farmyard manure would appear to be prejudicial rather than otherwise to the produce raised. It certainly could not be injurious judged of as a combination of elementary food substances. It is possible in a dry season that long "strawy" manure may not yield any of its virtues to the growing plants, and may, by its mechanical condition, alter the texture of the soil to its detriment for the time, but none would therefore think of condemning its use. It is only by repetition that we can make sure of eliminating all sources of error. Experiments in turnip growing are especially difficult to deal with. Every farmer knows the great irregularity sometimes found in a field of turnips as the result of ploughing on two different days, or of sowing the seed at different hours of the same day, all other conditions being precisely similar. When there are anomalous results on the same farm even in the same field, what can be expected of trials made at separate places under totally different circumstances? Considerations such as these should warn us against too quickly accepting the apparent teachings of a few experiments only, notwithstanding the care with which they have been conducted. Most important questions to be taken into account in field experiments are the previous condition of the land, the crops grown, the manures used, and the process of cultivation pursued during the five, ten, or more preceding years. It is at this point that the experiments of Mr. Lawes have been hitherto unique and unapproachable. The soil of his experimental plots is positively transparent, so to speak, from the minute details he gives of all its present state and previous conditions. He makes us familiar with its whole history. He explains its capabilities from practical experience, gives its quality and present condition according to analysis, or by an equally convincing process of reasoning from its past, until at last the soil plays him no tricks of disappointment, for he is able to predict almost to a nicety what will follow from the application of any given manure to any given plot. The Woburn experiments, based on a like method of procedure as has been adopted at Rothamsted with such excellent results, will afford an invaluable record of agricultural experiments. It will take some years before any teachings of a definitive character will be elicited, but, when obtained, they will prove of inestimable value. Meanwhile we would encourage agricultural bodies everywhere to make experiments for themselves, and thus add to the common stock of facts in relation to the growth of farm crops.

PRIZE FERTILIZERS.

RESPECTING the important display of fertilizing matters at the Paris Exhibition, what most struck the visitor was the absence of all show to attract clients. Manufacturers remained content to demonstrate that the preparation of artificial manures was not behind any chemical or mechanical industry, that the raw materials of these manures were sought for with intelligence, transformed and combined in a rational manner, with no secrets to conceal, and sold at prices proportioned to intrinsic value. The proofs were conclusive of the great development in the extraction in France of mineral fossils, in Belgium of the refinement of chalk phosphates; of the general preference for dissolved and pulverised guano in place of that fertilised in its crude state. Serious progress was shown to have been made in the torrefaction of animal refuse. However, the treatment of night soil, and its rational utilisation, leaves very much to be desired. It cannot but have also struck the observer how much commerce stood in need of a "common chemical language," for the various preparations which restore to the soil, azote, phosphoric acid, and potash—the three terms in use on the continent to express the value of a fertilizer, while in England, ammonia, phosphates, and the salts of potash, are the expressions employed.

It is only since 1840, when Liebig laid down the imperious law of restitution, that a veritable revolution ensued in the trade and manufacture of commercial manures. In France alone, three milliards of francs represent the annual sum employed in the fabrication, &c., of fertilizers France is also the richest country in the world in fossil phosphate of lime, that employed in agriculture being chiefly derived from the tertiary formation in the form of phosphorite, and as nodules, in the secondary strata; the latter are found in the neighbourhood of Lille, Mans, and in the departments of the Meuse, and Ardennes the former are chiefly obtained in Aveyron, the Lot, Herault, Tarn and Garonne, Beziers, &c. One firm, Desailly, commenced in 1850 to extract nodules in the Ardennes; since then, its operations have extended to other parts of France, so that at present it employs 1,000 workmen, and produces 20,000 tons of phosphate of lime yearly, of which one-third is exported. Some of the phosphates contain from 28 to 33 per cent. of phosphoric acid, and are largely employed in the preparation of superphosphates. The value of the mineral phosphates depends on their mechanical fineness, or pulverisation for the assimilation of a fertilizing matter is more rapid, as the points of contact are more numerous with the dissolving agents of the soil—water, carbonic acid, and organic matter. But there is a limit to the economic action of minerals in the shape of impalpable powder. Thus a ton of triturated feldspar rock, containing 10 per cent. of potash, and costing fr. 66, will be infinitely inferior to the salt easily obtainable in a cheaper and more concentrated state.

No doubt it is very laudable to extract phosphates from the bowels of the earth; to import guano from South America and Australia; nitrate of soda from Chili, and fish guano from Scandanavia. Not less important is the economic utilisation of the detritus of slaughter houses and knacker's yards, and of public markets. In Paris, cesspool matters afford annually 7,000 tons of *poudrette*, and 3,000 tons of ammoniacal salts. At Amiens, fecal matters have charcoal for the base of their *poudrette*, and the chopped refuse of flax and hemp. Velvet clippings, brewer's refuse, straw, wool and leather waste; this mixture, when enriched with assimilative phosphates, sells well. For years the *debris* of slaughter houses has been in much request in France. But industry entered the lists, and by its aid, the utilisation of blood, flesh, horns, hoofs, hair, skins, &c., has become a speciality in France. The firm Bourgeois, for example, contracts for the blood of the chief slaughter houses in this country, amounting to 13 millions of quarts annually, and they employ 260 persons to work it up into marketable products. The blood is dried by three processes; contains 13 per cent. of nitrogen, and is mixed with superphosphates in various proportions. Another Company farms the intestines, &c, of the killed beasts, and when manipulated, this *detritus* is sold in three classes. The average number of animals daily killed in the city *abattoirs* is, 700 oxen, 150 cows, 30 bulls, 400 calves, 6,000 sheep, and 500 pigs. But as horns, hoofs, hair, skins, leather, &c., require two or three years to decompose in the soil, their reduction to a pulverable form is indispensible—hence torrefaction is resorted to. The preparation of bones has many various methods of application, but none particularly new. On the west coast of France, sardine and mackerel refuse, with sea plants, are boiled, after being previously drained, in large boilers; then pressed into cakes while hot, and ultimately dried, and ground. The peculiarity about guano consists in its being rarely employed otherwise than in a dissolved state, thus permitting of a fixed rate of nitrogen, 12 per cent. generally, to be obtained; of late years, much of the Peruvian guano imported had not more than 2 or 3 per cent. of azote, and the farmer was invited to pay a uniform price all the same by the Peruvian Government. France does not manufacture either dissolved or pulverised guano, but supplies her demands from England and Germany. Farmers habituated to employ only farmyard manure, guano, &c, viewed with suspicion the use of chemical manures; the honor of destroying their prejudices under this head, is due to M. Georges Ville, only he rode his hobby to death by prescribing doses of chemical fertilizers, compounded on the data of the ashes of cultivated plants, to restitute the salts carried away, just as if we were certain of the conditions of a soil's fertility. Strange, not a manufacturer prepares artificial manures for the general market on M. Ville's principles. It was only in 1860 that Norway commenced to utilise the refuse of her herring, cod, and mackerel fisheries, &c, having by pressure and steam, succeeded in depriving the refuse of the oil and glue, which proved insurmountable obstacles to the dissolution in the soil of the phosphates and azotised matters. Fish guano is now prepared along sea coasts in every part of the world; on an average it contains six to seven per cent. of organic nitrogen, rendering in this form the action of the manure more slow, certain and generally useful, and 16 per cent. of phosphoric acid, but not in a state immediately soluble; hence the difference between it and ordinary guano, and the practical lesson, that it ought not to be employed as a top dresser, but harrowed into the soil, before the sowings.

BULANDSHAHR AGRICULTURAL SHOW AND HORSE FAIR.

THE following more detailed account of this Show has been forwarded to us by a correspondent:—

The seventh annual Agricultural Show was held at Bulandshahr on February 18th and following days, and was as successful, or even more so, than in the years preceding. The show was first of all started in the year 187[illegible] by Mr. Willock, the then Collector of Bulandshahr, and it owes its origin to a happy idea of his that the cultivation of good varieties of wheat might be stimulated, if zemindars were encouraged to exhibit samples of their produce and subscribe for prizes to be awarded to the most successful producers. There can be no doubt that the rivalry which such exhibitions give rise to is a powerful stimulus to agricultural improvement, sometimes indeed acting when mere self-interest would seem quite inoperative. The opportunities which are given to agriculturists of comparing the results obtained by them with those of their neighbours are of course most useful, since in this way experience is gained far more quickly and easily than is possible by individual and unassisted experiment. Seeing the great improvements which these shows are admitted to have led to in English agriculture, it is worth the consideration of Government whether it would not be advisable to give grants of money prizes for the promotion of agricultural exhibitions in different parts of the country, in the same manner as they are now being given at the various horse fairs recently started. As it is, the Bulandshahr Show is supported entirely by voluntary contributions, and it is a matter of no little credit, both to the official and non-official residents, Native and European, that they have carried out the scheme as originally started by Mr. Willock with yearly increasing success. The Show comprised exhibitions of agricultural stock, implements, and produce, horses and native manufactures. The latter were specially good, as might be expected under the auspices of the present

Collector, Mr. F. S. Growse, C. I. E. Specimens of the more notable native manufactures (Azimgarh pottery, Benares brass work, &c.) were exhibited, and in some cases distributed to persons interested in them; and the attention which has been paid to the subject has already borne noticeable fruit in the district, some articles exhibited by Bulandshahr draftsmen being specially good both in idea and workmanship. The exhibition of agricultural produce was very interesting, forming a collection of nearly all, if not all, of the various products of the district; and in some cases the samples exhibited were of extremely good quality, and showed careful cultivation. It is said that very many of the more intelligent cultivators have begun, far more generally than before, to *select* seed for sowing, setting aside the finest of their produce for this purpose, instead of going on the happy-go-lucky system which is generally followed. The agricultural implements exhibited were not remarkable, and native ideas do not appear to have been able to effect much improvement either in ploughs or water-lifts. It is to be suspected, however, that more good would result were Government to assist with a pecuniary grant, as the prizes could then be awarded with rather more indifference to the feelings of the exhibitors. As it is, most of the chief exhibitors are also contributors to the prize fund as well as judges on one or other of the various committees, and it is only to be expected under these circumstances that occasionally in their awards they are rather more influenced by their regard for the exhibitor than by the quality of his exhibits.

The show of horses was above the average, the occasion of the Show having been taken advantage of by Government to make Bulandshahr one of the district horse fairs, which are now held under the supervision of the Superintendent of Horse Breeding Operations. A good horse, therefore, had a chance of obtaining two prizes · one from the Government grant on the judgment of the committee appointed to award prizes from it, the other from the voluntary contributions of the district, which were distributed by a second committee.

Among the most noticeable things at the Fair were a McComa's water-lift, and an improved American plough, exhibited by the Department of Agriculture and Commerce, both of which were kept working from time to time, and attracted great attention. The high price of the lift, over Rs. 200, will, it is feared, bar its general adoption; but it has been found practicable to adapt the principle it acts on to a construction of wood and rope, which could be made up for a comparatively trifling sum. The plough, which is both light and effective, was much approved of, and numerous applications for ones like it were made. Since it can be constructed by any ordinary intelligent carpenter, Mr. Growse was wisely in favour of getting them made up in the district; but a large number were indented for as samples. A fact which tells for its future introduction is that the cultivator, whose bullocks were hired to draw it, asked for two on his own account.

The new form of sugar-mill, invented by Messrs. Thomson and Mylne, which has been so largely adopted in Shahabad, and a couple of Bull's dredgers were also exhibited, and showed to advantage.

The Show may be regarded as most successful from another aspect, for the pleasure it gave to the crowds of natives, villagers and towns-people, who frequented it. Most of the native gentlemen and proprietors of the district were encamped round the plain on which the Fair was held, and the opportunity afforded them of meeting each other seems to be much appreciated, and is said to have promoted freer and more intimate social intercourse between them than formerly existed. For the crowds of spectators the Show seemed to afford unending amusement, wrestling succeeded exhibitions of conjuring feats, and scratch horse races the wrestling; while illuminations and fireworks brought the last evening of the Fair to a brilliant close. Nothing happened to mar the arrangements, which were excellent throughout, and are most creditable to the district authorities. A special word of praise is due to the Tehsildar, Pundit Hurgyan Singh, to whose unremitting exertions the Show owed much of its success.

The crowds of well-dressed happy looking villagers were a marked feature of the Fair, and had one of our modern pessimists been present, he must have felt how lightly the people of India bear to all appearances their country's "bankruptcy."

THE DATE-PALM OF THE PERSIAN GULF.

READERS of the newspapers must have learned how the date-trade of the Persian Gulf has been increasing of late how the miners of the Black Country have taken to eating dates, how the Arabs themselves almost live on that fruit, and even feed their horses on it, while there are few in this country who do not know the taste of the luscious berry that finds its way to Calcutta in queer-shaped baskets, so different from the woody substance known to the Hindoos as the date. But there are few who are aware that the attempt to grow the Arab date in India has been successfully tried. The experiment originated under the auspices of a Chief Commissioner of Oudh, and the Conservator of Forests in Mysore and Coorg has also been supplied with plants. Some shoots have recently been sent from Busrah for experiment in Rajpootana, where the native date still grows in abundance, and we shall be glad to hear how they have succeeded. Meanwhile a memorandum on the system of cultivating the date-palm in the vicinity of Bushire has been written by Mr. J. C. Edwards, the 2nd Assistant Resident, from which we cull the following details:—

Offshoots which sprout round the foot of the female trees are procured from Busreh Katef or Bahrein, and transplanted to wherever the cultivator may desire to have a date grove. These offshoots may be procured of all sizes, but the smaller ones—say one foot high—are preferred. After being transplanted they require to be watered daily for two or three years. The soil in which they are planted should be soft and the base of the plant surrounded with manure. The manure used is horse dung mixed with earth and allowed to decompose for a year before being used.

Where water is plentiful the offshoots spring up rapidly and bear fruit within four or five years. But where water is scarce and the soil hard, ten or twelve years elapse before any signs of fruit are visible. Opinions differ in regard to the rearing of date trees from seed, but all agree that offshoots are the best, inasmuch as they take less time to grow and are far more strong and productive than the trees reared from seed.

The date tree first shows its blossoms in February, the cultivator has then to decide what number of branches he should leave on the tree and withdraws the superabundance. The number of bunch blossoms on each tree varies from 12 to 24, but it is seldom that more than 12 are allowed to remain for fruit.

At this period also the cultivator has to impregnate the blossoms of the female tree by joining thereto some portion of the blossoms of the male tree. This is done by simply depositing a sprig or two from the male into a bunch of the female blossom and lightly binding it up with a sprig. The male tree is distinguished by its blossom which is of a reddish tinge, while that of the female is milky white. The blossom of the male tree is only used for impregnating, and does not turn into fruit. It is averred that in places where the date palm grows thick together, the wind scatters the pollen of the male blossom, and that the female trees thus become impregnated with it, saving the cultivator further trouble on this head. When through neglect or oversight the female tree fails to be impregnated, it is asserted that the fruit it bears does not come to perfection, is seedless and insipid.

About May the fruit begins to form and from this time to September, when it is perfectly ripe, the tree sheds the superabundance which is used as food. At this period (May) the fruit is known as "Khumal" and is green in colour. In June or July it is known as "Kharek" and is either red or yellow. It is then fit to be eaten. In August it becomes soft and juicy and is known as "Ratab" but is not yet in a fit state for preservation, which it does not attain till September when it is known as "Khurma." It is then taken off the trees and gathered into a tank or trough exposed to the sun where it throws off its extra juice, and hardens sufficiently to allow of its being packed up in baskets and prepared for exportation. The juice is gathered and stored in skins or jars, and is used by the poorer classes in lieu of sugar.

There are more than a hundred varieties of date known by different names which it would not be easy to enumerate or describe, nor would there be much utility in doing so, for they are only understood by the natives of those parts to whom it is a matter of great consequence to know the the name of the date they purchase, as prices are regulated thereby. These latter vary in the ratio of 1 to 4. The best description of fruit is packed in skins of 70 to 120lbs., the average price being 15 krans (about Rs. 6) for the latter weight.

The poor feed on the droppings of the date palm from May to September, and keep the produce as food for the next 7 months, the branches *supply* them with fuel and material *for* hutting, the fruit branches when divested of the fruit are used as brooms, and the leaf turned into rope or matting, the stem is cut up and used in house building. Toddy is not extracted, as this people have not yet acquired a taste for that liquor.

AN ECONOMIC BUREAU.

NOT many months ago we mooted the question of an Economic Bureau for this province, and urged on the consideration of the local administration the advisability of establishing such a department. What we then said was, it should be the *special* duty of the bureau to give attention to the natural productions of the country as well as attend to the development and conservation of local industries. To-day the reasons are stronger than ever, and as the country advances these will be getting stronger and stronger. They have a public department in India for the purpose, but Imperial necessities are so many, large and various, that local wants as a rule do not receive that care and attention they deserve. Certain it is the wants of British Burma in this direction, have not been attended to as they require. The country is, comparatively speaking, new, its natural resources "legion," and what it needs is a special department, for the initiation and carrying out of measures that will develop these rich natural resources. There is a wealth of oil, wood, resin, minerals, in the country, of which the world in particular, and even persons living in it generally, know little. The other day only the olive was found growing wild in Tharawaddy; and so luxurious is its growth, that an Italian gentleman gave it as his opinion that the growth of olives in British Burma would open out a most remunerative field for speculation. While it takes fifteen years to arrive at perfection in Italy, the olive plants here are so forward that in five years they yield as much as plants elsewhere of fifteen years' growth. Then there is lac, and the narrative of attempts to establish its manufacture goes further than anything else to show the great need there is of a department such as is urged. Those who are familiar with the subject, will acknowledge the truth of this remark. Up to 1873, although lac was well known by the *people* to exist in the country, and although the manufacture of it was widely practised, none of our officers seemed to be aware of these facts, for when the question of the establishment of its manufacture was first agitated, other countries were asked not *only* for instructions how to treat the insects, but for the *insects themselves.* Yet all these years,

on the bushes and branches of some dozen varieties of shrubs and trees the insects might have been found all over the country in every district, even on the Arakan Hills. This is what Colonel Twynam says in a letter addressed to the Conservator of Forests some time back :—

The Chief Commissioner has read Mr. Strettel's paper with much interest. It has now been ascertained that the *Coccus Lacca* (The lac insect, ED. *W. R.*,) is to be found in nearly every district in Burma, including the Arakan Hills, from which a very fine specimen has been received, and valued by a leading firm here at Rs. 130 per 100 viss.

The matter is alluded to here not for the purpose of reflecting in an adverse way on any department, but just by way of establishing our contention regarding the necessity for a special department to attend to natural resources. Existing departments are too much burdened with work, and to expect any, even the Forest, to take up this additional work would simply be to expect what would never be attained. But from the above it will be seen that while there existed quite a wealth of one resource at home, no body, we are aware of, ever said anything about it, and the local administration in its ignorance sent across the seas for intelligence and material that was available at its very doors. A better illustration of darkness under the lamp would be hard to quote.

The same with regard to silk. The tussur moth exists here, as well as the ordinary silk, yet how little is done for that industry may be seen from the quantity of indigenous raw silk, annually exported. So also with gold. It abounds in the Malayan Peninsula, particularly in the Shwegyeen district and to the north of it, yet how little is ever taken to the market. So with coal, now stated positively to exist in the Ramree district.

It would be easy to fill columns of this paper with particulars of local resources and industries neglected and languishing, needing only a little enterprize to enrich the country and the speculator engaging in them. What is needed is that a knowledge of natural resources be disseminated far and wide in order to attract capitalists. And to do this effectually an Economic Bureau must be established. The Phayre Museum might very well be developed into one. An officer who understands these matters, and who will enter heart and soul into the work, ought to be entrusted with it. The present Secretary to the Agricultural and Horticultural Society is just the one to be placed in charge of such an institution. Intimately acquainted with the country and its productions, his large and varied experience extending over a number of years point him out as the very person to be entrusted with the care of such a charge. It need not be very large, nor need the initial and subsequent expenditure be great. A sufficient outlay from Provincial Funds will be needed in the beginning, and afterwards a small establishment will have to be entertained. The collections from visitors would go in some measure to lighten the cost of monthly expenditure and the produce of the garden would add to that. Mr. Aitchison will confer a boon on the province by the establishment of such a department, and we earnestly commend the matter to his consideration.

After writing the above we were shown a piece of pine wood, obtained by the late Mr. Nepean, from the forests in the vicinity of which he so lately lost a life that was abundantly fruitful in good work to a Government that did not appreciate him as he should have been appreciated. The existence of this pine, named by Dr King the *Pinus Merkusi*, was not known of till Mr. Nepean got it. It is so rich in resin that its growth would pay remarkably well, and if we allude to it here it is only to strengthen our contention for an Economic Bureau.—*Rangoon Paper.*

CINNAMON.

THE spice trade of India is not only a small one, but one that fluctuates a great deal. The exports consist of such as *cassia, pepper, ginger, cardamoms, chillies*, &c.; and the imports are principally *cloves*. Cassia is closely allied to cinnamon, and the trees of both, as well as their spicy products, greatly resemble each other. Cassia is also known as *bastard cinnamon*. India is capable to producing both plants, and a group of cinnamon trees is one of the pleasantest sights in the tropics. Except in Ceylon, the cinnamon plant is, however, rare in India, and its plantations when got up are attended to with much care. When the plants attain maturity, they acquire a commercial value; but they seldom grow beyond thirty or thirty-five feet in height. In form they are symmetrical, their trunk is smooth and the foliage dense. The leaves possess a fine polish, and are prettily and regularly veined. The tender leaves show a reddish color which time changes into a green hue. A plant putting forth young leaves looks at a distance like a huge bouquet of bluish-green, sprinkled over with pink. Its inflorescence is ordinary, the individual flowers being small, poor of color and inodorous. One would fancy that a cinnamon plant would be fragrant throughout; this, however, is not the case, and a whole plantation may be traversed without a breadth of spicy odour being perceptible. Bishop Heber is said to have declared :—

"After hearing so much about the spicy gales of Ceylon, I was much disappointed at not being able to discover any scent, at least from the plants, in passing through the cinnamon gardens."

On being bruized in any part, however, a distinct odour of cinnamon becomes apparent, and both bark and leaves taste decidedly of the spice. During the cinnamon season, which comes on after the departure of the rains, the gardens are quite odorous; for at such time the young twigs are cut off the parent stem, and the processes of barking, peeling, rolling the brown sticks proceed in all directions.

The cultivation of cinnamon is neither difficult nor laborious. All that is necessary to success is a hot, damp atmosphere, and a sandy soil, rich in decayed vegetable mould. Shade also is necessary. A locality satisfying all these particulars needs nothing more than to have the plants put down at convenient distances, and attention to such ordinary matters as occasionally stirring the soil near the roots and keeping the space round them clear of weeds. In six or seven years the bushes attain a height of six or seven feet; but no barking is done at such an age. The operation usually commences when the trees have attained a growth of some years, and it is one of the simplest of processes on the face of the earth. The young twigs, not *very* young, are first slit in a longitudinal direction, and next transversely, the bark is then loosened from the tender wood, peeled, scraped, sorted, packed, rolled, dried and put into bags of 80 or 90lbs. each as the cinnamon of commerce. A similar process is carried on with cassia bark. Cinnamon peeling begins in Ceylon at the close of the rains and lasts till November. The work is attended to by a particular caste of natives who are known as *Chulliahs*, and of them men, women, and children in scores, if not in hundreds, engage in the cinnamon gardens of Colombo.

The best "sticks" are from Ceylon; but Java, Sumatra and Cochin-China amongst others, produce the tree plentifully. The best Indian variety is that from the Malabar Coast; but the tree can be grown almost anywhere at no great distance from the sea-coast, provided the requisites of shade, drainage, a hot, damp atmosphere and rich soil are present. Such being the case it is possible British Burmâ possesses localities that would be favorable for the growth of the tree, and cinnamon as well as cassia introduced here. Young plants of both kinds might be put down in forest clearings in the best sities procurable. The preparation of the yellow pipes would not be difficult once success is attained in the matter of growing in the trees: the work would just suit the native population. Moulmein promises a better field for experiments in this direction. There the mangosteen and cocao grow, as well as varieties of the natural order *Myrtaceæ*. A few experiments with cassia and cinnamon might be tried without much expense or risk, for the prospect of gain is not inconsiderable if success be attained. The quantity of spice imported into Great Britain averages annually 850,000lbs. British Burma might be able to contribute somewhat to this annual average.

NEW COMMERCIAL PLANTS.

UNDER the above title, Mr. Thomas Christy, of 155, Fenchurch-street, has issued another of his pamphlets, which treats of products either quite new to commerce, or of those that have been for some time known but have not come into general use. These pamphlets demonstrate at once the truth that the world does yet contain a vast field of unappropriated wealth, and it is only by constant watchfulness, or a keen perception of what is really valuable, that the fine metal is separated from the dross, so to speak, and new commercial products are established in our markets. The discovery of new rubber-yielding plants, and the extended geographical range of well known species, are matters that have often been referred to in those pages, and in the pamphlet under consideration a new rubber plant is described, and figured under the name of *Urostigma bogelii*. Referring to this class of plants, Mr. Christy says, in his preface. A great many plants yielding india-rubber are now known to botanists, and more are being discovered every year. Comparatively few, however, are fit for general cultivation; some which yield excellent rubber do not produce an adequate return until after many years, others require certain peculiarities of soil and climate for their successful culture; while others, again, which possess the advantages of rapidly coming to maturity, and of being easily cultivated, yield a rubber of low commercial value."

There are, perhaps, few questions in economic botany regarding substances of such great commercial importance as india-rubber, where the plants producing them are involved in such mystery. It is to be hoped that by the energy of collectors abroad, supported by such men at home as the author of the pamphlet in question, a true knowledge may soon be obtained of these botanically and geographically widely diffused plants.

Mr. Christy draws special attention to the *Gynocordia odorata*, or the tree yielding the Chaulmugra oil, as one of the most important plants for introduction into all tropical countries, on account of the great therapeutic value of the oil obtained from the seeds. This oil has long been known, and valued highly in "India and China as a remedy for skin diseases and other complaints due to impurity of the blood, and as a specific for secondary syphilis. . . . . In the Mauritius it is considered to be the only reliable remedy for leprosy, and so high a value is put on its purity that the seeds are imported from India for the purpose of obtaining the oil free from adulteration. . . . .

The pure oil in India is expensive, and therefore offers a great inducement to the natives to adulterate it; indeed, adulteration is carried to such an extent, and is so difficult to detect, that it has occasionally caused medical men in India to discontinue its use. Preference should, therefore, be given, in purchasing the oil, to

that which has been expressed from the seed in this country." It is chiefly in the cure of consumption that this oil is now used, and is strongly recommended by many medical men of note. Among the public institutions where it is now in use may be mentioned St. Peter's Hospital, Berners-street, the Margate Infirmary, the Hospital for Diseases of the Chest, City-road, St. John's Hospital, Leicester-square, &c. From the satisfactory effect of this oil in many reported cases it seems that its general adoption is insured, as in India a good deal, nay, nearly all depends upon the purity of the oil supplied, and complete purity is guaranteed in the oil furnished by Mr. Christy.

Another plant of India which deserves more attention in this country than has hitherto been accorded to it is the Maliwall (*Bassia latifolia*), which is very abundant in all parts of India, both in a wild and cultivated state. The most valuable product of the tree is the flowers, which are produced in enormous quantities and fall to the ground so thickly when fully ripe as to form a dense carpet. These flowers are gathered each morning, and stored by the natives for winter use. They contain a large quantity of sugar, and a strong spirit is distilled from them, very similar in flavour to Irish whisky; this spirit has been proved upon analysis to be very wholesome, and when carefully rectified can be obtained exceedingly pure.

Such then are some of the products of the vegetable kingdom new to commerce in this country, the introduction of which are due to the energy dispayed by Mr. Christy.

THE PAPAW.

At a recent meeting of the Berlin Natural History Society Herr Wittmach, gave an account of some researches and experiments he had undertaken upon this subject, which are thus summarised in a recent number of the *Pharmaceutical Journal.*

"A perfectly ripe undamaged papaw fruit measures from 7 to 8 inches in length, and 3 to 4 inches in width, and has the appearance of a rather long melon; it has a beautiful yellow rind, which in its taste also resembles the lemon, though with a slight flavour of turpentine. The most interesting and important property attributed to it, however, is the power of its juice to rapidly render hard flesh tender.

"As far back as the year 1750, Griffith Hughes says, in his *History of Barbadoes*, 'This juice is of so penetrating a nature that if the unripe peeled fruit be boiled with the toughest old salt meat, it quickly makes it soft and tender, and if pigs be fed with the fruit, especially unripe, the thin mucous matter which coats the inside of the intestines is attacked, and if the food be not changed, is completely destroyed.' According to Browne, meat becomes tender after being washed with water to which the juice of C. papaya has been added, and if left in such water ten minutes it will fall from the spit while roasting, or separate into shreds while boiling. According to Holden the flesh of an animal hung to a branch of the tree is rendered tender. Kalston says that in Quito the use of Carica juice when boiling meat is very general, but in Venezuela and Costa Rica the practice is unknown. Some further experiments were made by Roy, who obtained by making incisions in a single fruit 28 39 c.c. of the milky juice, which after evaporating to dryness and again diluting with water, had a powerful action upon flesh, albumen and gluten, while starch remained unaltered by it.

"Herr Wittmach, the author of the present paper, obtained after repeated incisions of a half ripe fruit only 1·195 grain of white milky juice of the consistence of cream. This dried in a watch-glass to a hard vitreous white mass, having what appeared to be greasy spots on the surface, but what really were flocks of gelatinous substance, that always adhered to the more hardened material. The odour and flavour of the fresh juice recalled that of petroleum or of vulcanised India-rubber. The microscope showed it to be a fine gummous mass containing some larger particles and isolated starch grains. Iodine coloured the juice yellowish brown.

"A portion of the juice was dissolved in three times its weight of water, and this was placed with 10 grames of quite fresh lean beef in one piece in distilled water, and boiled for five minutes. Below the boiling point the meat fell into several pieces, and at the close of the experiment it had separated into coarse shreds. In the control experiments made without the juice the boiled meat was visibly harder. Hard-boiled albumen, digested with a little juice at a temperature of 20°c., could after twenty-four hours be easily broken up with a glass rod. Fifty grains of beef in one piece, enveloped in a leaf of C. papaya during twenty-four hours at 15°c., after a short boiling became perfectly tender; a similar piece wrapped in paper and heated in the same manner, remained quite hard. Some comparative experiments were also made with pepsine, and the following are the conclusions arrived at by the author:—

"1. The milky juice of the Carica papaya is (or contains) a ferment which has an extraordinarily energetic action upon nitrogenous substances, and like pepsine curdles milk.

"2. The juice differs from pepsine in being active without the addition of free acid—probably it contains a small quantity; and further it operates at a higher temperature (about 60° to 65°c.) and in a shorter time (five minutes at most.)

3. "The filtered juice differs chemically from pepsine, in that it gives no precipitate on boiling, and further that it is precipitated by mercuric chloride, iodine, and all the mineral acids.

4. "It resembles pepsine in being precipitated by neutral acetate of lead, and not giving a precipitate with sulphate of copper and perchloride of iron."

MANURE.

When manure is "fire-fanged," or overheated, the most valuable portion—the nitrogen—is driven off, although the mineral elements remain. To prevent overheating, it is not required to continually fork over the manure, but simply to compact the surface of the heap, and to cover it with a thin layer of earth. Unbleached ashes may be mixed with bonemeal, if care is taken to cover the mixture with plaster, or earth; and the action of the ashes will act upon the bones to reduce them to plant-food but, unless the earth or plaster is used, there will be a great waste of nitrogen from the bones. There is no climate in the world where manure requires more looking after to get any good from it than this, and yet of all places it is here allowed to lie exposed to the elements, to be bleached and washed clean of all its fertilising properties. There is more labour necessary to "lead manure" on the land for cultivation than will pay for this wanton and foolish waste. Manure, such as cow-droppings or goat manure, becomes almost useless if spread for any time on the surface of the ground, exposed to the sun and the rain, and yet at the present time, if our horticulturists or agriculturists wish to enrich their lands, they must either get a supply of this rubbish or pay heavily for a manufactured article, such as animal manure or superphosphate of lime and other artificial preparations. To utilize the cleanings of stockyards, measures must be taken to conserve the volatile and free elements of the manure, and the best means available for this is either a boxed-up space made with slabs above the surface of the ground, or a pit sunk in the ground, which, of the two, is preferable. Whichever plan is adopted, let it be remembered that manure to have a chance to do its best should be always moist enough to allow fermentation to take place uninterruptedly, and to prevent the dry burnings such gatherings are subject to. All experienced men are aware that these dry heats are utterly destructive to the best fertilizing qualities of the manure heap, and hence to prevent this on all high cultivated farms much labour is expended in frequent turning of the manure to check this. Whatever may be thought about this, or whatever neglect may be suffered under present circumstances, the time will come when cultivators will know that they must manure if they would reap, and this manure must be looked after to get any good from it. While manure heaps require to be moist they must not be where they would lose their soluble particles with floodings. A pit may easily be secured by using the earth taken from the excavation to form an embankment all round it, and the raised enclosure can also be protected by digging a trench round it to carry away surface water. In addition to these necessary precautions to save the volatile or perishable particles of the manure before it is used, it is equally necessary to take care that there is no more waste than is possible when applying it. As a rule manure should never be allowed to be for any length of time exposed on the surface of the soil without covering. When covered with soil, which is a powerful deodorizer, the waste is reduced to a minimum; and in any case manure should only be carted on the land when wanted for a crop about to go in or already in. There are many experienced cultivators who prefer to cart manure on land when crops are up, and then to cover it with the horse hoe or cultivator, or even in some instances they harrow it in—*The Inquirer.*

CARBON AS PLANT FOOD.

The great mass of vegetable matter is composed of woody fibre (cellulose), which consists of carbon 44 per cent., oxygen 49 62 per cent, and hydrogen 6 38 per cent. Nearly one-half of the vegetable growth of our forests and fields is, therefore, organised carbon. This substance is known to us in the form of charcoal, though the diamond is pure crystallized carbon. In its uncombined form, it is not soluble in any known liquid, nor is it fusible in any heat we have been able to produce. At red heat, it combines readily with oxygen in a brisk combustion, without flame, and the product is a gas composed at 27 per cent. of carbon and 73 per cent of oxygen, and commonly known as carbonic acid. It has a feeble acid reaction, and forms salts with alkalies. At the temperature of 60 degrees, water will dissolve and hold in solution its own measure of carbonic acid gas; but it parts with it all at a boiling heat. In this form all the carbon appropriated by plants is furnished, and it would be a very natural inference that to

furnish a supply of carbonic acid would be the first care of the farmer. But this would be altogether an erroneous conclusion.

From various sources, the air is always supplied with carbonic acid in sufficient quantities to answer the demands of plant growth; but the chief interest of the farmer is to place his crops in a favourable condition to appropriate the carbon brought within its reach. An animated dispute has been carried on for several years between two schools of vegetable physiologists—the one contending that all the carbonic acid used by the plant was absorbed by the leaves; and the other holding that a portion of it was supplied by the roots, being held in solution in the water absorbed. The question, however, is one of but little practical importance, as both parties admit that plants derive all their carbon from carbonic acid, and that the decomposition of that gas takes place in the leaf.

The important matter, practically, is to understand the conditions under which vegetables appropriate carbonic acid; for this is the secret of their growth. These conditions are chiefly two: first a healthy condition of the leaf; second, a full exposure to sunlight. The first of these is that which chiefly concerns us. Leaves absorb carbonic acid in proportion to the amount of green colouring matter they contain. This, as I have always said, depends on a supply of nitrogen in a form that the plant can use it.

Ammonia dissolved in water and absorbed by the roots is the usual form in which the supply of nitrogen is obtained. This is decomposed in the leaf by the agency of sunlight, and the nitrogen, set free, immediately enters into a new combination, and the green colouring matter is the result. But this change demands the presence of potash and phosphoric acid, in very minute quantities, indeed, but still essential. A deficiency in any one of these conditions will give a pale or yellow leaf, and every farmer knows what that means, though he may not be able to explain why it is so. But plants absorb no food, by the leaf, in the dark, and there is no chemical action in the absence of sunlight. It is true that plants grow at night, but they grow by using the material prepared in the light and by its agency.—R. T. Brown, in the *Country Gentleman's Magazine.*

THE GEOLOGICAL SURVEY OF INDIA.

THE following Government Resolution has been sent to us —The year under report was comparatively unproductive of fresh work. Mr. Lydekker continued his explorations in Kashmir, but in consequence of the famine there, and of a temporary indisposition, he was prevented from carrying out his projected visit to the Gilgit region, and was obliged to content himself with making an examination of the sedimentary rocks of the mountains of Dras and Tilail. Mr. Hacket also again carried on his investigations in the Aravalli Range in Rajputana. Mr. Fedden and Mr. Foote broke new ground during the season, the former in Kattywar, where a large extent of country was surveyed, and the latter to the south of Trichinopoly. Mr King was employed in working out the connection of the formations mapped by him in the Lower Godavery district with those mapped by Mr. Hughes on the Pranhita; and Dr. Feistmantel visited the Satpura coal-basin with a view to examining on the ground some good sections of the Gondwana series. In the Punjab, Mr. Wynne made a preliminary examination of some new ground in Hazara, having been prevented by difficulties on the frontier from following the formations of the Salt Range across the Indus into the Bannu district, as had been proposed, while Mr. Theobald added largely to the collections of the Sewalik fossils in the Geological Museum.

2. In Palamow, two new coal-fields were traced out by Mr. Ball in the basin of the Koel river; but the coal of these areas is said to be not so good as that of the Daltonganj field lower down the Koel. In December 1877, Mr. Mallet was deputed to report on some coal seams in Ramri Island, which had been brought to notice by the Commissioner of Akyab; but an examination of them did not lead him to form a favourable opinion of their practical value the coal is said to be inferior to that found in Bengal, whilst the measures are greatly disturbed and difficult to work.

3. Mr. Medlicott himself was chiefly occupied in directing the work of the survey, and in editing its publications. In February 1878, however, he formed one of the Committee which had been appointed to investigate and report on the causes of the deterioration of land by *reh* in the Aligarh district; and while in the neighbourhood, he took the opportunity of examining two cases of the supposed discovery of coal in the Sewaliks of Dehra and Nahun, with the result that the reports which had been made were proved to be fallacious.

4. Mr. Blanford's time was fully taken up in the work of compiling the "Manual of the Geology of India," the preparation of which was directed at the close of 18.4, and which the Government of India are glad to learn has at length been completed. The object of the Manual is to place before the general public in an intelligent and popular form the results which have been attained by the Geological Survey of India; and imperfect as a preliminary work of this nature must necessarily be, it will supply what has long been felt to be a great want, and will, moreover, serve as a nucleus from which, in course of time, the survey will be able to develop a more complete record of its scientific labours and discoveries.

5. Owing to the circumstances explained at page 12 of the Report, only one number of the *Memoirs* was published during the year; the *Records*, on the other hand, were fuller of matter than usual: they extended to three times the size originally contemplated, and contained numerous outline maps. Two large parts of the *Palæontologia Indica* were also issued, one on the flora of the Jubbulpore group by Dr. Fetismantel, and the other on the crania of fossil ruminants by Mr. Lydekker.

ENGLISH FRUIT TREES IN MANIPUR.

THE Political Agent of Manipur in his Administration Report for 1877-78, says:—

During the last cold season I have introduced the following English fruit trees, &c., with a view to acclimatizing them in Manipur, *viz.*, apple, pear, plum, peach, apricot, Himalayan apricot, cherry, currant, quince, vine, raspberry, Spanish chesnut also deodars and three kinds of Himalayan pine.

With a view to giving them a thorough trial, I have planted the above in two gardens, one in the valley at a height of 2,570 feet above the sea, and the other in the hills at 5,250 feet above the sea.

Notwithstanding the difference in temperature and rainfall many of the young plants seem to do equally well in both places; this applies especially to apples, plums, apricots, and pears, though owing to the more stimulating climate, those in the valley have grown much more quickly than the others. The Spanish chesnut however seems to prefer the cooler climate, and while those in the hills are doing well, the one planted in the valley is languishing. Cherries I have only tried in the hill garden, and of five trees none are really flourishing, though at first they promised to do better than any others. I intend trying some in the valley next year. The quince flourishes in the valley and so does the vine, while the currants, raspberries, and rhubarb are doing admirably in the hill garden. The deodars and pines evidently prefer the cooler climate of the hills and there, if the winds allow them, will do well, but those in the valley are at present very little inferior in appearance.

It is much to be regretted that the experiment of introducing English fruit trees was not tried long ago, as any time since the opening of the railway to the north-west it would have been easy to procure them, and had a commencement been made ten years ago Manipur might now be producing really fine fruits.

There is every reason to believe that apples will eventually succeed well, as a species of wild apple, far from despicable for cooking purposes, grows well in both the hills and valley of Manipur. For the same reason it is to be hoped that apricots and plums will do well, as an uncultivated kind of both these fruits grows and produces luxuriantly in the valley. I believe that the existence of the apricot in Manipur has never before been noticed by any one; it is rather strange that it should be found here as it is unknown elsewhere nearer than the Himalayas; it seems therefore probable that it was brought in former ages from China, when intercourse between that country and Manipur was frequent. The raspberry of Manipur grows in both hills and valley, and is of three kinds, *viz.*, yellow, red, and black. Dr. Brown mentions the existence of the blackberry, but I have never seen it, and think that he must have mistaken the black raspberry for it.

EXPERIMENTAL FARMING IN MYSORE.

THE Secretary of State for India a short time back called for information relative to the steps that had been taken in parts of India to impart to the agricultural classes generally the lessons to be learnt from model or experimental farms. With reference to this, the Chief Commissioner writes that in Mysore "no general steps have hitherto been taken in the direction indicated, the condition of the province during the past two or three years having forbidden any such measures. Mr. Harman, the Superintendent of the Bangalore Farm, has recently been authorized to make tours in the province twice in the year, once in the summer when the *ragi* crops are being sown, and again during the winter months when crops are being reaped, in view to his acquiring practical experience in the native systems of agriculture, and imparting to the ryots by personal communication and by experiments the benefits of deep ploughing, as also the advantages to be gained by the use of improved seed."

The Chief Commissioner has also under consideration a scheme for placing one or two plots of land in each district under the charge of a village patel or other suitable person, who would cultivate the land in accordance with instructions from Mr. Harman. 'By this means,' the Chief Commissioner observes, 'it is hoped that the ryots will have an opportunity, which the location of the Government Farm at Bangalore does not afford them of judging of the results to be obtained by a better system of farming.' Since these remarks were written, however, it has been decided to abolish the Bangalore Farm, and to transfer the services of Mr. Harman to the Bombay Presidency." Mr. Harman is now out in the coffee districts with a view to enquiring and reporting upon the coffee leaf disease. We trust the local Government will be able to see its way to retaining his valuable services in the province.

SUGARCANE AT BELLARY.

A CORRESPONDENT from Bellary writes to a contemporary :— In many parts the crop of rice has been fully gathered in, and the only standing crop now is sugarcane, which is very extensively cultivated on land lying under the different channels. In every village one passes by, or through, just now, he sees either the mills at work or being constructed, boiling houses erected—very temporary ones, of course,—and boiling going on. The work not only goes on "from morn to dewy eve," but far into the night, and is again begun in " the wee sma' hours ayont the twall." Each member of the "united," though not always happy, "family" taking his share or round of duty.

The mill is a very premature piece of mechanism. It consists of a pit and a foot-board firmly fixed in the pit with two upright wooden pillars cut near the top into a male and female screw. One pillar is stationary and the other is worked with the usual lever by bullocks. The top of the pillars are secured by a collar piece securely fixed on upright, bedded deep in the ground. The stalks of cane are inserted in the female screw upon which when the mill revolves is entered by the thread of the male screw, and so the juice pressed out. The lever pole is very long, and the rear end being heavily weighted the pillar forms the fulcrum. The mill is worked or turned by four, six, or eight bullocks. The refuse of the cane is stored up for manure, as also the ashes from the furnaces, where the boiling is carried out. The leaves prove good and fattening fodder for the cattle.

The produce is from very coarse jaggery to fairly good sugar, according to the degree of attention paid in the manufacture, some never attempting to refine at all, but disposing of it in its roughest condition, packed up in bags made of date leaves, for which there is a great demand at present. The boiling is carried on, "as aforesaid," in temporary sheds, in iron pans from 8 to 12 feet over and from 1 to 1½ foot deep. These cost from sixteen to thirty rupees each, and do not last very long.

The sugarcane growth and sugar manufacture is not confined to land lying under the channels, but is largely cultivated on land under the tanks, especially in the valleys where the soil is good and the percolation from the hills very free. There is now such a briskness displayed by the agricultural classes that a stranger would never believe that the district had but a few months since escaped from the throes of a famine. This sugar manufacture will keep the people employed until the next sowing season commences about April next. Meanwhile the channels will be clear from silt, and the various masonry works repaired.

THE FIRST EMPLOYMENT OF GUANO.

IN an interesting paper on this subject which has recently appeared from the pen of Professor Kohl, the author takes occasion to point out that the employment of guano in agricultural operations is by no means of such modern origin as many of us are disposed to believe. So long ago as the twelfth century the Arabian geographer Edresi called attention to the existence of cliffs covered with the excrement of birds in the Persian Gulf, not far from the famous pearl fisheries of the Bahrein Island, and relates how this dung was collected and despatched to Bassora and up the Euphrates to be used as manure for the orchards, vineyards, and date-groves on its banks. So, too, from the earliest ages the semi-civilized Peruvians made use of the deposits of guano on their coasts for the improvement of their husbandry, and so well was its value in this respect recognized that their white Incas decreed severe punishment for any one killing the birds that produced it. According to our author it was Humboldt who first drew the attention of Europe to the rich deposits of the Chincha Islands in the early part of the present century, but his voice remained long unheeded. It was not until the year 1840 that a ship-load of guano was despatched from Peru to England at the risk of the enterprising firm of Quiros, Allick and Co., of Lima. Experiments were instituted as to its effects on wheat, potatoes, and oat crops, on fruit trees and on flowers, with such wonderfully favourable results that a general demand for the new manure soon arose in England, France, Belgium, and Germany. Hundreds of ships set sail for the Chinchas in search of cargoes of guano, and for many years the Peruvian Government derived an annual income of 16,000,000 dollars from its sale. The depth of the deposits was in many places a hundred feet, and their total value was estimated at £42,000,000 sterling. But even this was at last exhausted, and then commenced the quest for fresh supplies. England first discovered them on the Lobos Islands, and on several parts of the South American coasts as far down as Patagonia, as also on the South African island of Schaboe. The dread of an exhaustion of the known supplies was so great that formally organized expeditions to all parts of the world were undertaken in search of further deposits. The Red Sea itself was ransacked, and a Russian merchant, established at Archangel, sent out an expedition to the Polar Sea, and overhauled the Island of Kolgujew, and the peninsula Kadin. Meanwhile the island groups of the South Sea were diligently searched both by British and American. In the *Journal* of the New York Geographical Society, for 1859, it recorded that up to that time no less than forty-nine islands and groups of islands rich in guano deposits has been discovered by American explorers, and their latitude and longitude accurately determined, and some of these that till then had been uninhabited since the day of their creation were suddenly developed into densely populated centres of untiring industry. In our own Continent, too, the search was diligently prosecuted, and rewarded by the discovery of rich deposits of bones coprolites, and bats' guano, all of high manurial value.

VALUE OF WOOD ASHES AS MANURE.

THE experiments carried on with bleached wood ashes in America continue to be favourably reported on, and to win more friends every year. They have been used for many years by the farmers and market gardeners of Long Island, and later by the same classes in the sea-coast towns of Connecticut, and also on the tobacco farms further inland. Bleached ashes contain considerable quantities of potash and phosphoric acid, which have a wonderfully invigorating influence upon exhausted soils. The onion-growers make large use of ashes, buying them sometimes by the thousand bushels. Fruit-growers are much pleased with its effect upon the growth of trees and shrubs, and upon their productiveness. Their effect is said to be immediately visible in old pastures and meadows, sown broadcast as a top-dressing ; but they act still more satisfactorily if applied to the crops at the time of seeding down. They not only largely increase the crop with which the grass seed is sown, but their influence is visible for many years afterwards in the increased yield of grass. A farmer who has used ashes freely for twenty years upon a hard, worn-out gravel soil says they will give an increase of hay upon a meadow newly stocked for eight years ; and then, if the field be ploughed again, they will show the effect of the ashes for six years longer. He applies about 100 bushels to the acre, on land that he designs to keep in permanent meadow, and about 75 bushels to pasture land. It is particularly satisfactory as an application to a rye crop, even in so small quantities as 20 bushels to the acre. He has reclaimed a large breadth of old fields given up to the growth of bushes, briers, and brakes, and made it a fine pasture by taking rye crop manured with ashes.—*The Journal of Forestry and Estates Management.*

CHLORIDE OF LIME AS AN INSECTICIDE.

THE virtues as a disinfectant of that impure mixture of hypochloride of lime and chloride of calcium, met with in commerce as chloride of lime, are probably known in every household, but its value in gardening operations, or in agricultural work on a larger scale, as a destroyer of vermin, meets with less general recognition. In calling attention to this subject, our contemporary, *Le Cultivateur*, remarks that if a little of this salt be spread on the soil, rats and mice and insects will at once desert it. By its means plants may easily be protected from insect plagues by simply brushing over their stems with a solution of it. It has often been noticed that a patch of land which has been treated in this way remains religiously respected by grubs, while the unprotected beds round about are literally devastated. Fruit trees may be guarded from the attacks of grubs by attaching to their trunks pieces of tow smeared with a mixture of chloride of lime and hog's lard, and ants and grubs already in possession will rapidly vacate their position. Butterflies again will avoid all plants whose leaves have been sprinkled over with lime water.

GARDEN.

MR. JAMIESON, Superintendent of the Government Botanical Gardens, Ootacamund, reports that the case of strawberry plants imported by Mr. H. B. Grigg, C. S., from Australia were quite dead on arrival at the Neilgherry Hills. Each plant was examined carefully, but not one had the slightest vestige of life left, being all completely rotten. Mr. Jamieson regrets the entire loss of what would have been a valuable importation, especially as the plants had been packed with the utmost care and at considerable expense. He suggests that a collection of Nilgiri orchids would be much valued in Australia ; with the permission of Government he will be glad to make up a case of the rarer varieties to be forwarded to Sir William McArthur in consideration of the trouble and expense incurred in packing and forwarding the strawberry plants.

SALICYLIC ACID TO PRESERVE FRUIT.—There appears to be no end to the long list of valuable properties with which salicylic acid is to be credited. It cures nearly all the ills that men and live stock are heirs to, as well as many that they acquire, and it enables milk and cream to set time and temperature at defiance. The latest testimonials in its favour relate to its power of preserving fruit

The process as described by M. A. dal Piaz, of Klosternenburg, near Vienna, is extremely simple, and consists in laying the fruit in jars of syrup containing a small percentage of the acid. The proportions recommended are 2 or 3 grammes of salicylic acid and 100 to 500 grammes of sugar to a litre of water. No boiling or cooking of any kind is required. Berries and stone-fruit of all sorts thus treated will keep good for months together, or even years, without the slightest approach to fermentation, even when the vessels containing them are but insecurely covered, and will preserve their natural aroma unaltered. Boiled fruit-juices will keep equally well with the addition of one gramme of the acid to every 2 lbs. of the juice, and with such addition the colour of the latter is altered in the cooking. The only precaution needed is to secure pure crystallised acid of the finest kind, for the inferior varieties impart an unpleasant flavour to the fruit.

AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

The Annual General Meeting was held on Thursday, the 27th February 1879.

THE HON'BLE LOUIS S. JACKSON, C.I.E.,
President, in the Chair.

THE proceedings of the last meeting were read and confirmed.

The Report from the Council was read and adopted. The Report enters first into the internal economy of the Society, shewing that after deducting for deaths, resignations, and departures from the country, and allowing for elections during 1878, the total real number on the books is 690, which includes Honorary, Associate, Corresponding, and Life Members. The financial position is much the same as in 1877. The best acknowledgments of the Society are due to his Honor the Lieutenant-Governor for the continuance of the monthly grant of Rs. 200 for another three years. The Report then proceeds as follows :—

"Among the members who have been removed by death during the year, Mr. Francis Halsey of Sujanpore in the Punjab, deserves special mention. He died of typhoid fever in August last at Venice on his way to England. Connected with the Society for 15 years, he had been in frequent communication on a variety of useful subjects, some of which are rec[illegible]d in the Proceedings. During more recent years he had turned his attention specially to silk and sugar cultivation in the Punjab, which promised to result favourably. Shortly before his departure from India, he took an active part in the exhibition of silk cocoons held at Nurpur in the Kan[illegible]ra district, and furnished the Government with a report thereon of considerable interest. The Society, many years ago, encouraged this industry when quite in its infancy and awarded a medal to a native zemindar in the Punjab, who had taken much interest in its promotion. 'No unofficial gentleman,' observes the Secretary to the Government of the Punjab, in a communication to the Government of India, Department of Revenue, Agriculture and Commerce, 'has labored with more interest and success to improve the native industries of the Punjab, and his enlightened exertions for the improvement of the breed of cattle, the introduction on new staples, the development of sugar manufacture, the rearing of the silk-worm, and the manufacture of silk, have been, on many occasions and in various reports, brought under the notice of the Government of India." On his last visit to Calcutta, in the early part of the year, he promised, as soon as he could command the necessary leisure, to contribute certain papers to the journal, the result of his proceedings towards the development of the silk and sugar industries of the Punjab, which, had he been able to com[illegible] them, would no doubt have been interesting and useful.

"The death of Mr. Sulpiz Kurz, Curator of the Herbarium of the Royal Botanic Garden, Calcutta, though he was not a member of the Society, cannot be omitted in this annual record. Mr. Kurz had on various occasions contributed papers to the journal, and his latest, and most valuable on the *Musaceæ* published in Vol. V. Part 3, has been left unfinished by his untimely death in January last at P[illegible]aang, whither he had proceeded in the hope of restoring his health. His botanical researches in the Malayan Archipelago, Burmah, and India have been considerable. His death in the prime of life has deprived science of an unassuming but most ardent votary.

"Work has been well attended to during the past year in the Garden.

Applications for delivery orders (233) have been duly met. Besides these, many supplementary orders have been issued, a fact which shows that many members have availed themselves of their privilege of indenting on the Garden. Of ornamental plants, 8,000 have been distributed to members and of economic plants 4,619, besides sales to members and others of 2,500 fruit grafts, and 1,115 ornamental plants. The demand for rose plants has been so great as almost to exhaust the old stock; and as this class of plants continues to be so popular, it is proposed to introduce next year (1879) a further stock of new varieties.

"The Council has to express their obligations to various correspondents for donations to the Garden; among these may be mentioned the Queensland Acclimatisation Society, the Directors of Botanic Gardens at Mauritius and Singapore, and Mr. T. M. Francis; and for seeds to Dr. King, of the Royal Botanic Garden, Calcutta, the Baron Ferdinand [illegible] Mueller of Melbourne and Mr. H. E. Abbott of Tirhoot.

"A flower show was held in the Garden, the first of the kind in this locality; and though it took place so late in the season as the 2nd of March the collection of plants exhibited was tolerably fair, and the attendance of visitors, members, and others, was large. The amount received by sale of tickets, at one rupee each, from the latter almost sufficed to meet ordinary expenses. This was the first occasion on which a charge was made for admittance; but the innovation passed unobserved, or at least without objection. Ladies and children were admitted free.

"Allusion was made in the last Report to a very important subject, namely blights of various kinds affecting the tea plant, and to the efforts which the Society were making to organize a full inquiry towards its thorough investigation. These efforts have been continued during the past year. Several Agents, largely interested, were quite willing to support the proposed scheme, provided others would join. As however these have failed to respond the Society have been reluctantly compelled to abandon it altogether.

"The demand for useful plants and seeds has been unusually large during the past twelve months, and has been responded to the best of the Society's ability. Among others may be recorded applications for tea and tobacco seeds from Rangoon, Arracan, and the Andamans; Bamia cotton seed for the Bangalore Botanic Garden; seeds of various kinds from the Director, Department of Agriculture and Commerce, N.-W. Provinces, and from the Minister of Public Works in Egypt.

"Various subjects of interest have been communicated and discussed during the year, more especially in respect to sericulture, flax cultivation for the sake its fibre, manures for tea gardens, Arabian date palm *quoad* its cultivation in India, and the utilization of certain plants in times of scarcity, and several others, of which full particulars have been recorded in the monthly Proceedings.

"Two parts of the Journal, 3 and 4 of Vol. V. have been published during the year, and Part I, of Vol. VI. is now in the Press, and will probably be issued in the early part of 1879."

The election of Officers and Council was next taken up with the following result :—

President.—The Hon'ble Louis S. Jackson, C. I. E.

Vice-Presidents.—Mr W. H. Cogswell, Mr. W. Stalkartt, Rajah Suttyanund Ghosal Bahadoor and Baboo Kali Prosonno Ghose.

Secretary.—Mr. A. H. Blechynden.

Council.—Baboo Peary Chand Mittra, Mr. E. Broughton, Mr. R. Blechynden, Mr J. W. O'Keefe, Dr S. Lynch, Mr. W. Waterfield, Baboo Protap Chunder Ghosa, Mr. J. E. MacLachlan, Dr Geo King, Dr. J. B. Barry, Mr. S. H. Robinson, and Mr H. J. Leech.

Baboo Protap Chunder Ghosa's name, was added to the Tobacco Committee; the other Standing Committees need no strengthening, and remain, therefore, as in 1878.

The following gentlemen were elected members :—

Messrs. T. T. Leonard and W. St Clair Grant, the Managers of the Lallacherra Garden, Cachar and of the Paikpara Estates.

The names of the following gentlemen were submitted as desirous of joining the Society :—

A. Wilson, Esq., Merchant, Calcutta,—proposed by Mr. W. H. Cogswell, seconded by the Secretary.

Syed Fazlur Rohman Mogulpara, Patna,—proposed by the Secretary, seconded by Mr. S. H. Robinson.

Alister Mackintosh, Esq., Dooreea Factory, Tirhoot,—proposed by Mr. H. E. Abbott, seconded by Mr. T. M. Francis.

Mr. Narsing Row, Zemindar, Vizagapatam,—proposed by Mr. T. H. Mosley seconded by the Secretary.

Leitchfield Moseley, Esq., Manager, Dooars Tea Company, Julpigoree,—proposed by Mr. J. Mackillican, seconded by Mr. S. Cresswell.

W. M. North, Esq., Proprietor, Bogracote Tea Estate, Silligoree—proposed by Mr. Cresswell, seconded by the Secretary.

B. H. Carew, Esq., Assistant Manager, Dim-Dim Garden, Julpigooree,—proposed by Mr. Cresswell, seconded by the Secretary.

Prince Mahomed Furrock Shah Russapugla,—proposed by the Secretary, seconded by Mr J. E. MacLachlan.

Manager, Hunplann Hill Estates, Seebsaugor, Assam, proposed by the Hon'ble A. B Inglis, seconded by the Secretary.

Baboo Narendra Narain Roy, Zemindar, Jemoosh Kandhi, Moorshedabad,—proposed by Dr G. King, seconded by Mr. J. E. MacLachlan.

Rejoined.—Hon'ble H. T. Prinsep, Calcutta; Capt. J. F. Pogson, Simla; Howard Lawin, Esq., C. E., Midnapore; W. C. Tresham, Esq., Cawnpore, and E. A. Thurburn, Esq., Calcutta.

GARDEN.

The Head Gardener's report was submitted, of which the following are extracts :—

"The work since last report has been of a miscellaneous character, the general tidying up of the garden grounds occupying a considerable share of our attention. Propagation and potting of various plants still continue. In looking over the contributions made to the garden, I find that the violets sent to us by Mr. T. M. Francis of Tirhoot are looking very healthy. The seeds of Blighia Sabida sent from Cawnpore farm were somewhat immature, and though they germinated, the seedlings were weak and died off in the course of a few days. I have noticed from the trees in our garden that the fruit nearly always falls to the ground before attaining the size it ought to attain, the fruit is exceedingly pretty, and should be used as a vegetable, whilst small and tender; its specific name is well deserved. The

Australian seeds, presented by Captain C. J. Wilkinson, have, in some few cases, germinated, though they have been sown since 23th August 1878. I noticed in the flower garden that Petunia, Lobelia, and Verbena seeds have germinated vigorously after having lain in the garden soil since last spring; I expect this is owing to their exclusion from the air: this throws some light on the preservation of seed packed in the earth for import. The rose garden has been smartened up, but many plants having died a long time ago, causes it to shew too much soil in *proportion to flowers*. It would be an improvement to re-introduce the same direct from England. If we re-import these roses, we might get *some new kinds also*,—a few caladiums, crotons, dwarf habit palms, *&c.*, and also Liberian coffee seedlings, in large quantity. A portion of the garden might be set apart for their cultivation, as this coffee is eagerly looked for by members and others interested in its introduction on a large scale into India. We should, I think, take as much interest in its introduction as private parties, who, though willing to order for themselves, have not the same facilities of communication as we must of necessity have from our long experience. We have only a few plants in the garden, and what few seeds they give, produce plants after an extremely long interval—the supply being quite inadequate to the demand. Plant houses are being cleaned and regulated and general preparations are being made for the protection of plants during the coming glare of the hot weather."

TOBACCO.

Read a report from Messrs. Anderson, Wright & Co. on some tobacco submitted by Mr. O'Conor of the Department of Revenue, Agriculture, and Commerce. The plant was grown at Myouk-toung in Arracan Hill Tracts, and cured at the Government tobacco farm at that place by Mr. Schoenemann, the Superintendent. The tobacco is considered a good article, not unlike what is known in Calcutta as Hinghlee and which is much appreciated by the Ooria buyers. For export in the present state of prices in Europe it would be but of little value.

COTTON.

Read the following report from Mr. W. H. Cogswell on certain specimens of cotton (New Orleans, Upland Egyptian, Bamia, Naukin, Hinguughat) raised in the Saharunpore Botanic Garden, and forwarded by Mr. Duthie, the Superintendent :—" I have very carefully examined the samples of cotton grown at Saharunpore Botanical Garden, which I consider most creditable. I should have been better able to give more of a detailed report had some of the cotton been removed from the bolls ginned in the usual way and the seed removed. I place opposite the names of the samples the classifications, as I think the trade would accept them in England, on the assumption that they had been grown in the countries from which the seeds has been imported and not in the garden above-named, as I am of opinion that the quality is very little, if any, inferior to those descriptions grown on their own soils."

Read another report from Mr. Cogswell, on some cotton raised in the Meerut District, by Emtar Ali Khan, a Zemindar, from seed brought from Mecca, and of which a small sample was previously received, too small to report on. " This sample as now seen in quantity," observes Mr. Cogswell, " is not at all like the small sample sent to you in a letter. It is very red, most irregular in staple, the bulk of it being almost worthless, here and there portions of staple equal in length and character to Rangoon ; anything but a desirable article of commerce, and probably not worth more than Rs. 8 to Rs. 9 a maund, as against Rangoon at Rs. 14 to Rs. 15. From its very mixed quality and condition, I think it has been badly prepared, and that more might be made out of the seed under a careful cultivation, picking and ginning."

CROCODILE OIL.

Read the following report from Dr. Kanny Lall Dey, on a sample of Crocodile oil received from Mr. Purcell of Agra. Mr. Purcell intimates that if of any commercial value, he could obtain a large quantity of this oil.

" I submitted to comparative examination the Crocodile oil with other animal oils, with the following result :—

" Crocodile oil contains a larger proportion of solid fat than either the Neats-foot or Codliver or other fish oils. It solidifies at the melting point of ice, while Neats-foot only slightly thickens, and the others scarcely thicken. I have also tried the softening quality of the various animal oils on leather, and on comparison I find the leather treated with Crocodile oil remains much stiffer than others treated with other animal oils.

From the above results I do not consider that Crocodile oil has as much commercial value as Neats-foot oil."

LAC ON TEA BUSHES.

Messrs. A. R. Mackintosh & Co. sent some cuttings from tea bushes at Lizziepore Garden, Kurseong. The Manager thought the bushes were being covered with lac, but this seeming doubtful, they ask for a report thereon. The Secretary stated that he had referred these infected twigs to Mr. Cogswell who had obligingly reported on them :—

" I have examined the small twigs of the tea bush which bear a deposit and for which you seek a name. It is most difficult to do so. It is an unmistakeable resin and I am half inclined to think that it is the deposit of the lac insect, kermes lacca or ' Coccus, laccus' It contains dye or slight coloring matter to a very small extent only, as the enclosed test I have made will show. That, however, may be attributable to the fact that the insect had only just deposited the eggs which had not time to mature when the branches were cut.

" I may mention that these remarks refer to the twigs that you first sent to me, from a portion of which deposit I made the experiment not to the accompanying ones. A close inspection of the two will show you that the difference is in the latter sample having the deposits of a greyish white color and much less matured than the former.

" I am sorry that the deposit is not more matured, that fact renders this opinion somewhat uncertain.

NEW MODE OF MULTIPLYING PLANTS.

Read the following letter from Mr. T. M. Francis, in continuation of his previous communication submitted at the General Meeting in November last :—

" With reference to my letter, describing the American process of striking cuttings of hard-wooded plants by burying them upside down I have now the pleasure to report on an experiment which I have made.

" On the 19th December 1878 I buried 20 bundles of cuttings, taken from the prunings of my rose trees. The roses so treated were *(inter alia)* Alba Rosa, Beauty of Waltham, Deuil de Prince Albert, General Jacqueminot, John Hopper, Jaune D'Or, La France Marechal Niel, M. Ravil, Mme. Charles Vardier, Mme. Laffay, Murrillo, Prince Camille de Rohan, Reine des Violets, Solfaterre, and Souvenir de Wm. Wood. I only put down a few cuttings of Marechal Niel and Solfaterre as I was doubtful whether they would succeed.

" On the 5th February 1879, I disinterred the cuttings by turning the box which contained them upside down, (I must premise that the box had been left during the above period exposed to the sun, the earth being moderately watered every morning and covered with a *jhâmp* or mat every evening.) As each bundle of cuttings was taken out, I put its lower end into a pail of water in which the cuttings were carried to a spare bit of land which I had previously enriched with *koonee*, *i. e.* well rotted indigo refuse. Here the cuttings were sorted and planted out at intervals of six inches. Those which were dead or had failed to form a callus, were put aside in a basket. When the planting out was finished *all* the cuttings were carefully counted. The result is as follows :—

Cuttings originally buried	437
Failures	107
Callus formed on	330

" This may, I think, be regarded as a success, and the results would have been still better, but for a tame mongoose of mine which scratched away the earth from the cuttings on three several occasions, thus exposing the lower ends, which were of course uppermost.

" Every callus was well formed, and in most cases the leaf buds were well developed and ready to start. In some cases they had actually started and were pushing towards the light, so that they were obliged to reverse their natural growth.

" In many cases I found that a callus had formed at *each* end of the cutting. I selected six of these for a further experiment and cut them in halves, planting the lower ends in the plot of ground which I had prepared and putting the upper ends into flower-pots with good soil. I will let you know the result of this experiment. If it succeeds, I can claim the credit of raising plants from cuttings *planted* upside down. I shall be glad to know if this has been done before. My horticultural library is limited, but I cannot find in it any account of this reversal of the laws of Nature, having proved successful in its results. The six cuttings, thus treated, are of course distinct from the 330 on which a callus had formed ; and if they take, I may claim a further success

" Hence-forth I shall always use the American process for hard-wooded cuttings, and I trust that my success will induce many other Members of the Society to give this process a trial.

" About half the cuttings of Marechal Niel and Solfaterre succeeded well, I rejected *all* doubtful cuttings in order to give a fair report."

Letters were read :—

" From F. Moore, Esq., India Museum, London, respecting some diseased tea leaves (red spider) from the Tukvar Tea Co. Gardens, Darjeeling—(*See* proceedings for September, last.)" These tea leaves, " remarks Mr. Moore," are infested with a species of coccus, which is apparently, quite new both as to its attacking tea and in regard to its species, so far as I have been able at present to determine. In the small perforated tin box which was also duty received, and in which you mention was an insect from the Cossipore Tea Garden in Cachar, which was found by Mr. Edgar on a partially eaten tea leaf, I could find no vesting of an insect. This doubtless escaped through the perforations during transit. I much want to get good specimens of the *Psyche* or case-bearing insects which is stated to attack tea plants. Will you kindly send me specimens, if possible, of both the cases and the moths ; the latter particularly'. "

From Colonel W. H. Lowther, Benares,—presenting a paper on Capsicum and Chillies (Transferred for Journal).

From E. Buck, Esq., Director, Department of Agriculture, North-West Provinces, forwarding reports of trials of the Prickly Comfrey at Saharunpore and Kumaon. Transferred for Journal.)

Mr. Lynam sent for inspection a well grown plant, in flower, of *Oncidium (sphacelatum majus ?)*

Mr. Manukjee Rustomjee, also sent for inspection, an unusually large specimen of a native pumpkin or bottle gourd—native name *Laoo* (*Cucurbita Lagenaria*.) This pumpkin measures 4 feet 9 inches in length.

Baboo Protapa Chundra Ghose placed on the table specimens of tobacco, sun-cured, fire-cured and air-cured, and cigars made therefrom, which he considered the best he had seen. This tobacco was raised and prepared at Messrs. Begg, Dunlop, & Co.'s plantation a Poosa.

FORESTRY.

It is stated in the *Proceedings of the Californian Academy of Science*, Dr. Kellogg knows of only two trees which are perfectly proof against the Teredo navalis or pileborer of tidal water. These are the Palmetto, Chamærops Palmetto, and the Australian Eucalyptus rostrata. The Teredo will attack the wood of Eucalyptus globulus, and many other species.

A Giant Tree.—A patriarch of the forest has been lately felled in California, and the greater portion of the wood taken to San Francisco. It was known by the epithet of "Old Moses." If one might infer with accuracy its age from the number of its rings, it must have been 4,840 years old. Its capacity is said to have been so great that 360 persons could find room within its trunk.

Fever Trees.—Chr. D. Van Lennep, Swedish Consul at Mahazik, near Smyrna, writes as follows to the *Times*:—The cultivation of the willow is recommended by one of your correspondents for districts affected with malaria. His statements on the subject being fully borne out by my own experience in the well known malaria regions about Ephesus, I beg, through your columns, to call thereto the attention of the authorities in Cyprus. Before the *Eucalyptus* was ever heard of in Asia Minor, I had seen the bark of the willow used as a febrifuge.

It has been announced that the following gentlemen have been selected by the Secretary of State for India from the candidates who presented themselves for preliminary examination in November, to undergo the usual course of training in a French Forest School, to qualify them for appointments in the Indian Forest Department:—Messrs. F. S. Barker, O. E. Brasier, E. S. Carr, M. H. Clifford, J. H. Lace, and J. Rawbone. It is said that both as regards the number and attainments of the competitors, there was an advance on previous years. There were about forty applicants, for the five appointments which were advertised, and six nominations were made.

Forest products of China.—The northern provinces of China are very little wooded, with the exception of Sh'engking, which still possesses forests of oak, comprising about three varieties—*Qurcus obovata*, *Q. Mongolica*, and *Q. Castaneæfolia*, and also *Pinus sinensis*. The last tree is found nearly all over China. The first do not exist in the north, but in descending southward we meet at Ningpo Cunning *Lamia sinensis*, and *Abies kaempferi* We find abundantly grown at Shantung, the *Paulownia imperialis*, and *Catalpa bungeana*. The Cypress and the *Thuja orientalis* are grown as shade trees in the cemeteries and serve to make coffins. Lower down are found *Rhus cotinus*, and *R. semialuta*, the *Rhus vernicia*, which furnish the famous lacquer or varnish of China, and the *Elaeococca*, the seeds of which yield an oil. The poplars are chiefl found to the north of the Yangtze, where there are four species—*Populus tuyang*, *P. venusta*, *P. coriacea*, and *P. acuta*; their light wood is employed in the construction of junks. In the central provinces, besides the oil-tree *Elaeococca vernicia*, we also find the tallow tree, *Stillingia sebifera* and the vegetable wax-trees, *Rhus succedanea*, *Ligustrum glabrum*, and *L. japonicum*. In the neighbourhood of Shanghai, Soochow, and Kiangsu large plantations of mulberries *Morus alba*, are met with, the leaves of which nourish the silkworms. Further still we find the paper mulberry *Broussonetia papyrifera*. The pods of *Gleditchia sinensis* furnish a native soap. The wood of *Memia asadirachta* are employed at Canton for cabinet work That of *Laurus camphora*, which is found in Southern China, and especially in Formosa, furnishes by distillation the camphor of commerce, and is also employed to make boxes to keep clothes and furs in, as its odour is obnoxious to insects. The *Cassia lignea* of Kwangtung and Kwangso, furnishes a bark somewhat similar to cinnamon, which is much employed in Chinese cookery. These two provinces, as well as Yunnan, and the islands of Hainan and Formosa, have the bread-fruit tree *Artocarpus incisa*, the areca-nut, cocoanut, and other palm trees, the wood and leaves of which are much employed in building, for making fans, &c. *Chamaerops excelsa* and *C. Fortunei* produce a sort of fibrous thread, employed in making cordage, brushes, &c. Of the plantain there are in Formosa more than twenty varieties and on the coasts of that island and of Hainan, we meet the pandanus, the mangoe, the banyan fig, the *Ficus repens*, and other tropical trees.

TRAINING OF YOUNG FORESTERS FOR INDIA.

(*To the Editor of the Journal of Forestry.*)

Sir,—In a correspondence on this subject between the Indian Government and her Majesty's Secretary of State for India, we have in a communication marked No. 6, dated Calcutta, 1877, the following paragraph (para. 21):—"The art of planting larch and other coniferous trees has been brought to great perfection in Scotland, and is well understood in many parts of England, but forestry in Great Britain, we are informed [a saving clause], is limited to empirical skill in certain operations which succeed well under certain conditions of soil and climate. There is no system and no science of forestry in Great Britain, and the forest estates being with few exceptions private property, and are much smaller than the State forests of France and Germany, the student educated in the forests of Great Britain could only under the most favourable circumstances learn certain operations, the success of which [*sic*] based entirely on empirical knowledge, and the advantage of this sort of knowledge in India would be insignificant." This is a severe reproach to British forestry. According to the Indian Forest Department we depend entirely on chance for success. That forestry in Great Britain has no more claim on the science of arboriculture than is regulated by soil and climate, and that our science and practice of forestry is limited to the planting of larch and other coniferous trees. It must be admitted that we have not studied the science of forestry as much as we ought to have done, but it is a libel to state that our arboricultural knowledge is purely empirical; we have men as well posted up on the physiology of plants, who are quite as able to treat on plant pathology empirically and mechanically as can be found anywhere else. Talking of what the students learn at Nancy, we have it stated in para. 20 of above communication that "they learn it is possible to protect and manage State forests efficiently though they are not fenced. They become familiar with the natural regeneration of forests [this is stated to be of paramount importance to India], and they learn to understand and to respect the management of extensive forests according to a regular detailed plan of operations." Every intelligent forester will concur with me when I term this a mere course of elementary training, and in principle it is thoroughly understood among British foresters. Again, we have on the authority of Dr. Schlich, the Conservator of forests of India, that "the training necessary cannot be learned anywhere else out of India." At the same time he admits that "the two years' training at Nancy gives young men such an insight into the principles of forestry that they are at once able to be useful in India, and they come prepared to acquire in a short time more practical knowledge." The bare fact that after two years' training in a school of forestry young men have only got an insight into the principles of forestry will I should think, stagger some of your correspondents who are clamouring for a British School of Forestry. No, the time has not come for that yet, but if the Scottish Arboricultural Society would inaugurate competitive examinations, making it absolutely necessary that a certain standard of proficiency in the elements of geology, botany, chemistry, and mineralogy, must in every instance be attained by pupils having a practical knowledge of all the various duties connected with estate management, the Secretary of State for India could then have no difficulty in selecting his annual complement of five young men well qualified to proceed to India. I hold that the science of forestry is in every country and clime identical, although its application slightly varies under different circumstances. A British forester trained from boyhood acquires a thorough practical knowledge of the culture and management of trees, their adapation to soil, their physiological properties their habits, growth, and their relative value, nor does the scope of his experience end here; even though we have men at the present day arguing that young foresters ought not to trouble their heads with anything outside the planting of trees, he is taught to lay out and superintend various works besides those solely forestal. Although having stated this much, I am not to be taken up as recommending young men to be kept as mere drudges, as I regret to say they must feel themselves according to our present system, spending years of their time learning not a *science*, but a *mechanical art*. I therefore repeat what I stated in a former letter, that by the Scottish Arboricultural Society issuing an exhaustive code of instructions, and instituting annual examinations, the same will act like an "open sesame" to India.

D. SYM SCOTT.

Ballinacourte, Tipperary.

THE EFFECT OF COAL TAR *vs.* QUICKLIME ON UNDERGROUND TIMBER.

(*From the Brazil and River Plate Mail, Dec. 7*).

At the Framwellgate Colliery, some time since, an experiment was made to ascertain the comparative preserving power of coal tar and quick-lime upon the underground timber, as compared with each other, and with unprepared timber. On September 29, 1849, three larch tramway sleepers, each three feet long, two and a quarter inches thick, and five inches wide, were selected, and placed in the air course of the Hutton seam. No. 1 sleeper was prepared by receiving two coats of coal tar, No. 3 was in its unprepared or natural state. The three sleepers were supported at their ends by small pillars of bricks, and weighted in the middle with fifty-six pounds of metal. On January 6, 1852, the unprepared sleeper was found broken and quite decayed. On November 1, 1854, the sleeper prepared with tar was found broken and decayed. On December 23, 1856, the sleeper coated with lime was

discovered in a similar condition. From the above it appears that No. 3, or the unprepared sleeper, broke after two and a quarter years exposure. No. 2, or the tarred sleeper, broke after five and a half years. No. 1, or the limed sleeper, broke after seven and three quarter years. And that the sleeper prepared with tar had a duration of 2·84 years beyond the unprepared one, while the white washed sleeper survived the same for five years, and the tarred one for 2·16 years.

THE FLORIDA ALLIGATOR TREE.

THE noses of *Eucalyptus globulus* and of other *Eucalypti* are out of joint! It has been discovered that the Florida Alligator Tree will not only destroy malaria, but that branches or even twigs, if kept in the rooms of our dwellings, will prevent all sorts of diseases whatsoever. No wonder, then, that of late hundreds, in fact thousands, of happy men, and ladies, and children might have been seen passing to and fro the streets of great New York with a branch of the Alligator Tree in their hands. In almost every street bundles of these have been offered for sale at five or ten cents for each branch—"take your pick." "The great Alligator Tree of Florida. It will cure anything, Sir You have only to put one of these branches in your room. It will exude a sweet, balsamic odour which purifies the atmosphere and bids defiance to disease!"

In the moist delightful woods of hill or valley of the Northern States running westward to Illinois and southward may be found the Sweet Gum. Its leaves are like those of the Maple, except that in the autumn they change to a deep purple, sometimes beautifully mixed with orange. When bruised, the leaves emit an aromatic odour at all times, but in the spring, just after they are unfolded, and especially after a shower, the air is redolent "with their refreshing odour." The gay grey bark, especially upon later growth, is curious for its corky ridges that sometimes form corrugated plates an inch in width Its botanical name is Liquidambar Styraciflua. Millions of trees may be found within fifteen miles of New Jersey. But how could our city people be expected to know that! When *they* go to the woods they are too enraptured over everything to notice anything in particular!

When, therefore, twigs of Liquidambar Styraciflua are offered to them in the streets of New York as the Florida Alligator Tree, and they are assured of their wonderful powers, is it not quite natural that they should buy a twig or so for ten cents each and hasten on to their homes with a lighter step? *American Paper*.

AUSTRALIAN TREES IN CEYLON.

WE are much indebted to a correspondent who writes on the altitude at which blue gums may be expected to grow, but the latitude of Portugal must be taken into account, and there is cold to counter-balance the exceptional heat noticed. In Europe the *Eucalyptus* grows at sea level, and it is frost which has to be guarded against and not heat In India the blue gum will not flourish on the plains, even so far north as Lucknow. Here, in Ceylon, we have never seen the blue gum growing under 3,000 feet, though we have seen it flourishing on Horton Plains at 7,000. There is one of the most beautiful and most valuable of the Australian trees, however, which will ultimately be one of the most valuable additions to our scenery and our timber resources We refer to *Grevillea robusta*, specimens of which are pretty common in Colombo—notably at Mr. Cecil Ferdinand's house, in the Cinnamon Gardens, and which are readily recognized by their exquisitely beautiful fern-like foliage The *Grevillea* will not stand the full force of the sea breeze like the *casuarinas*, but will grow close to the sea if sheltered. There is a tree in front of Villa Sorento, on the Kollupitiya road, which proves this. Travellers by railway will notice a handsome group of *Grevilleas* opposite the Peradeniya railway station When up country at the end of last year we found *Grevilleas* which had been planted at a bungalow in Upper Dimbula in June 1873, throwing out rich tufts of deep orange-coloured blossoms, and we suppose seed has followed From considerably older trees at Mount Vernon bungalow, self-sown seedlings had been obtained, and the Peradeniya trees were shewing blossom and seed. The *Grevilleas* are seeding in many other places, so that now there is the prospect of a plentiful supply of locally produced seed of a tree which is superior to the blue gum for purposes of ornament and use. It is a capital break wind, and the timber is highly valued in Australia. The reasons why the blue gum (*Eucalyptus globulus*) is so general a favourite are that the seeds germinate freely and the trees grow so rapidly. But the trees are liable to be blown down or broken, much more so than the *Grevillea*, which we have seen at 4,700 feet altitude, becoming a fine well-grown tree, producing blossom and seed at a little over five years old. The gums, both blue and red are valuable, but other Australian trees and trees from other countries should not be neglected. The time is rapidly approaching, we suppose, when supplies of seed from locally grown Australian trees of the best quality will be plentiful.—*Ceylon Observer*.

AVENUES ON DISTRICT ROADS.

MR. CHAS. S. NOBLE writes to a contemporary.—I have recently seen the great success that has attended a simple measure adopted eleven years ago by a former deputy commissioner in the Unao district, a measure by which the district roads there have, to a larger extent than I have as yet seen elsewhere in Oudh, been provided with well grown avenues of mango and mahua trees. The trees too are remarkable for their straight, vigorous growth (a feature rarely seen in avenues planted and reared by Government officials), showing how perfectly they have been preserved from injury by cattle. The plan that secured this desirable result was as follows —Zemindars and cultivators were invited to plant trees upon the roadsides, and were assured that Government would in no way interfere with the planter's right of property in the trees Many persons accepted the invitation, and, as I have already described, their labour and care has worked, and is working, a great public good. Trees, as they grow to maturity, make the soil on which they grow unfit for other crops, and, for this reason zemindars do not encourage their ryots in planting trees in khets that border Government roads. I make the following suggestions, which, if adopted, might perhaps induce many cultivators to plant useful fruit bearing trees on sides of Government roads. Tehsildars and managers of Courts of Wards' estates should make it known in those villages that lie near district roads 1 — That permission will be given to plant trees "within" the road boundary, at a distance not exceeding 3 feet from the edge of the road 2 —That "sanads," signed and sealed by the deputy commissioner, will be given to each person who wishes to plant, specifying the number of trees to plant which permission is given, and the particular bounds within which they are to be planted. 3 —That a register of such "sanads" will be kept tahsilwar, perganawar and mouzahwar at sudder, and at each tahsil, in which register all changes of proprietorship in the trees will be noted as they occur 4 —That the trees to be planted will be limited to (I) mango, (II) tamarind (III) mahua, (IV) jamun, (V) kathal or jack fruit. The form of sanad might be as follows —

SANAD.

Ramdin, age 30, Kurmi, resident of Pirpur, son of Kalidin, is hereby given permission to plant 28 trees within the limits of the Government road leading from Rae Bareli to Garbakhshganj. The site for the trees is as follows - On the east side of the road 14 trees from Khasra No 167 to Khasra No 199 of Mouzah Pirpur. On the west side of the road 14 trees from Khasra No. 209 to Khasra No 237 of the same mouzah. The trees are to be planted not more than 3 feet within the extreme edge of the road, and the thalas are to be 15 yards apart from each other. The trees are to be mango, tamarind, mahua, jamun or kathal (jack fruit). All the fruit and income from the trees will be the absolute property of Ramdin Ramdin shall not at any time cut down or lop the trees without first obtaining the permission of the deputy commissioner. Ramdin shall have the power to sell or mortgage his title and interest in the trees and he shall notify the fact to the deputy commissioner within 15 days of sale. Should Government have to lop boughs, or to cut down a tree althogether, the value of the wood, after deducting cost of cutting will be handed to Ramdin.

Some improvements on this scheme may suggest themselves to district officers, but such as it is, I send it to you with a request that you will kindly publish it in your paper *pro bono publico*.

The Planters' Gazette.

TEA.

ACCORDING to returns presented to the Government of India, there were in 1876 77, in the Madras Presidency, forty-four tea estates at an average elevation of from 3,500 to 8,000 feet. The acreage "under mature plants," was 1,514, "under immature plants," 1,628. In addition to this area, 2,341 acres have been taken up for planting, but have not yet been planted. In the whole of India in 1876 77, there were about 130,000 acres under mature plant

THE *Indian Tea Gazette* informed its readers some time ago that "a noticeable feature in relation to the tea industry in Ceylon is the formation of a central manufactory in Colombo for tea from estates in the Island The leaf is sent down withered, and is then manipulated. The experiment is only to be regarded as a safe one if the withered leaf can be delivered in reasonable time." From enquiries we have made in Ceylon we find that this information is not correct. The leaf is manufactured at the estates and sent down to Colombo where there

is an establishment for *bulking* the tea, similar to establishments at the principle export stations of China tea. The central manufactory in Colombo is a bulking house.

It is not at all improbable that tea will before long be exported in a compressed state. Machinery of a very interesting kind, is in operation at the factory of Messrs. Goundry and Co., in Upper Thames-street, London, for the purpose of compressing tea into that solid form which has been found to be the most convenient for stowage, and in many respects advantageous to consumers. Of late, testimony has been borne by high authorities to the important benefits which are to be derived from the system of crushing tea in so forcible a manner as to preserve all its qualities, while greatly diminishing its bulk. The tea before being pressed is put up in quarter-pound parcels, and each machine employed in this work turns out 9,000 packages, or one ton per diem; and a pressure of no less than 40,000 tons is brought to bear on every 140 lbs. of tea. Hydraulic machinery of compound power, which is obtained by a patented appliance, enables this pressure to be exerted within a very short time, and the rapidity of the process is one of the great advantages possessed by this Company as a defence against imitation. In the presence of a few connoisseurs and experienced tea-tasters, a trial was made of the Goundry compressed tea against the same leaf as that from which it is formed—with the results that a portion of the tablet, weighed against tea in a loose state, was found to yield a liquor of much deeper colour and strength. At the same time an infusion was made from loose tea, 50 per cent. of weight being added; and this was about equal to the yield of compressed tea, which was but two-thirds the quantity. Then a second draw was tried; and though it might have been expected that an exhaustion of the crushed tablet had followed on the first brew, such was by no means the case, the relative results being the same on repetition. As to flavour, it appeared as if the process of compression, which had so remarkably changed the colour of the tea from deep black to an autumnal green, had likewise restored the leaf itself by the fracture and blending of all the internal particles to that virgin freshness of aroma which is agreeable to all tastes.

The fifth annual report of the Phœnix Tea Company of Cachar Limited, has been submitted to the shareholders, and we observe therefrom that the year has been fairly successful.

Had severe blight not attacked the garden generally, and a hailstorm not devastated the second division (Appin) in early spring, the outturn would have been considerably exceeded, and the profits proportionately enhanced.

Careful manufacture however has made up for the difficiency in the crop, by producing good marketable teas, that have sold well.

The expenditure has been somewhat greater than estimated, but this was *partly* due to the high price of rice ruling in the province, *partly* to the unhealthiness of the season, thus increasing the force of sick and feeble, and *partly* to cost of extra extensions undertaken, after the last report was issued, which was not provided for in the estimates.

Besides the 28 acres of garden opened out and planted prior to January 1878, other 50 acres of low lying flat land were drained, and are now being planted out from old *reserve nurseries* of "hybrid" seedlings, which, when yielding, will give handsome returns.

It appears that there are some hundreds of acres of this description of land on both divisions, that can be reclaimed, and made available for tea cultivation.

The system of shipping the teas direct to the Home market has worked most satisfactorily; not only have the chests arrived in good condition, but the weights have been fully maintained. Result seldom experienced in Calcutta bought teas A Dividend of 7 per cent. has been declared.

The operations for the ensuing season are well advanced: Pruning is nearly finished and all the gardens are under good cultivation: buildings are receiving the ordinary annual repair, and most assuring accounts have been received from the managers as to future prospects.

The estimates for 1879 are as follow :—

Estimated crop at "Bundookmara" 1,950 maunds=1,56,000 lbs. valued at 13 annas per lb.... .. Rs.	1,26,750 0 0	
Estimated crop at "Appin" 700 maunds=56,000 lbs. at 13 annas 6 pie per lb. ... ... ,,	47,250 0 0	
		Rs. 1,74,000 0 0
Expenditure at "Bundookmara" Rs.	65,300 0 0	
Ditto "Appin" ... ,,	26,207 0 0	
		Rs. 91,507 0 0
Surplus over Factory expenditure ... .. ,,		82,493 0 0
After deducting cost of stores and agency charge, &c. ,,		25,000 0 0
Estimated nett profit for disposal of ...		57,493 0 0

Calculations which the Directors have good grounds for believing will be realised.

The Directors observe at the close of their report :—

"The rates of 'Bonus,' given to time-expired coolies for renewal of agreements, have been greatly reduced, and we hope in time to see this objectionable and burthensome item of expenditure entirely abolished.

"The introduction of machinery, and the stoppage of extensions in the province—by lessening competition—have brought about a better feeling, and established a higher tone throughout the district, which is much to be lauded."

COFFEE.

A CACAO planter in Trinidad states that he has trees which yield him 15, and even in very good years 18 lbs. of clean dry cacao, at a gathering. This is a great but not an incredible yield, since Purdie got an average of 11 lbs. at one gathering from some old and neglected, but re-trimmed and properly cleaned trees in the garden, and Lunan—1814—relying probably on Blume—1672—says the annual produce in Jamaica's cacao period, two centuries ago, was generally estimated at 20 lbs. a tree, and averaged, good and bad seasons together, 1,000 lbs. per acre (=8 lbs. a tree, at 18 ft. apart—the usual distance there, at that period), although in poor soil, and under bad management, the yield per tree rarely exceeded 8 lbs. a year. Cacao cultivation in Jamaica died out in consequence of the excessive duty then imposed on it at "home," and the wretchedly small consumption of that day, partly owing to that fiscal imposition; and only now is painfully and with effort struggling to regain a place as a regular cultivation. It is very far from being worthy as yet of coming under the title of a staple of the old Colony.

From the last annual Report on the Government Garden at Rangoon we observe that the experiment of introducing and acclimatising Liberian coffee has up to the present time been entirely successful. On the 4th August 1877, the Agri-Horticultural Society of Madras sent to the Government Gardens at Rangoon 50 very small plants of Liberian coffee, which had been originally sent out from Kew. These were distributed as follows :—

Agri-Horticultural Society of Rangoon	18
Dalhousie Park at Rangoon	6
J. H. Gilbert, Esq., Rangoon	6
Commissariat Office, Thayetmyo	6
Government Gardens, Rangoon	11
Died	3

The 11 plants retained by the garden were kept in pots until the 22nd May 1878, when they were planted out on a sloping piece of ground, the site being selected with the view of trying various degrees of shelter, from perfect shade at the one end, to full exposure at the other. Small pits were dug, and, the soil being very poor, little manure was added; but no unusual care has been taken of the plants, it being considered best to grow them under the conditions to which they would be subject in an ordinary plantation. From a height of 12 to 18 inches when first planted out they have now increased to 2½ and 3 feet, with fine healthy deep-green leaves, some of which are over a foot in length. A further report on these plants, we observe, will be made next year. The ordinary coffee shrub (*Coffea Arabica*) has long been growing in the garden: it flowers and fruits annually, but can hardly be said to thrive.

A correspondent writes to the *Ceylon Observer* :—"A Liberian coffee plant, one of a few planted out on trial on an estate in this valley, has just blossomed. This plant was some 5 inches high, with two pairs of leaves, when planted out in November 1877, and in August 1878 threw out its first primaries, then 2 feet 9 inches high. It has now, in January 1879 (height 5 feet 2 inches), thrown out a few blossoms, and most of them have set.

Three of the other plants on this estate are from shoots, which were removed from young trees, and immediately put into pots. These are now fine healthy plants over 3 feet high, and were only planted out in September last year. Liberians, therefore, would seem to thrive in this valley.

Some cacao nurseries have been laid out with the view of their being planted next season, and will no doubt receive a fair trial, for good forest is now being felled for the purpose, besides plants intended for vacancies in patches of cocoanut.

The effects of the dry weather are already visible throughout the valley. Fences of *endaru*, at other times full of leaves, are now nearly bare, and branches of the cocoanut are found drooping on all sides, the young bearing trees seeming to suffer most.

The new road from Kotadeniya to Mugurungampola has been completed, and is already adding to the railway receipts at its station at Mirigama. It is to be hoped that the few remaining bridges put up in the *primitive* style (of jungle sticks covered over with earth) will shortly be replaced by more durable ones, otherwise the road will soon be impracticable for wheel traffic. It has already a heavy cart traffic of staves for casks sent to the railway for despatch to Colombo.

COFFEE LEAF-DISEASE.

THE following letter which Mr. Morris has addressed to the Hon'ble G. A. Talbot and which is published in the *Ceylon Observer*, gives further information respecting the efficiency of flowers of sulphur as a remedy for leaf disease:—

"Royal Botanical Gardens, Feb. 13th, 1879.—After working out a series of experiments with Mr. Wall's fumigating process and noticing the great vitality of the filaments and spores of the *hemileia*, even after applying fumes which almost destroyed the foliage of the trees, I thought it desirable in the interest of the great consequences involved to go carefully over my former experiments in order to place the efficiency of flowers of sulphur as a specific for leaf disease beyond question.

"Dr. Thwaites was also very anxious to observe the various stages of the experiments, and apply such crucial tests as might enable him to speak with confidence and authority respecting the value of flowers of sulphur as a specific for coffee leaf-disease.

"We accordingly devoted the greater part of this week to critical examination of leaves from sulphured trees. I hope to give fuller details of our work at a future date, but you will no doubt be glad to learn that the conclusions arrived at in our experiments at Wallaha have been very fully and satisfactorily borne out. Dr. Thwaites desires me to say that he is *completely satisfied* that flowers of sulphur can be applied with every hope of success in checking the ravages of the pest which has so long affected coffee enterprise in Ceylon.

"Though the effects of flowers of sulphur on the trees were very gradual during the present dry weather, we watched with great interest its slow, but certain action upon the filaments and spores of the *hemileia*. In no instance were the young leaves, the buds or the blossoms affected by the application of sulphur, and the result of our observations lead us to believe that if flowers of sulphur be generally applied to coffee trees, this year ought to see a great diminution of leaf disease on all well cultivated estates."

LIBERIAN COFFEE.

AT the last monthly meeting of the Madras Agri-horticultural Society, the Secretary read a letter from James Grant, Esq., Manager, Scottish Indian Coffee Company, Limited, Colachel, Travancore, dated 12th December 1878, forwarding the following interesting report on the Liberian coffee plants sent to the Company on the 16th August 1877, written by one of the Company's Superintendents:—"Owing to the case having miscarried and being broken in transit, only twenty-five of the fifty plants forwarded from Madras were received alive at Strathmore Estate. On breaking the small pots, the tap roots were found to have become very much twisted and entangled with the fibrous rootlets, in their endeavours to find an exit from the small pot in which they had evidently been too long confined. Great care had, therefore, to be exercised in transplanting so as to disturb, as little as possible, the soil in which they had arrived. The tap roots, owing to their great length and twisted condition, had to be freely pruned and dressed previous to transplanting; but, as has since been proved, this would appear to have acted beneficially in promoting their rapid growth, as, of the whole twenty-five plants received, all are alive and are shewing marked signs of their adaptability to the soil and climate in which they are now flourishing. Holes, about two feet square, were made for their reception, in a small piece of forest land clear ed specially for the purpose, and were filled with virgin soil from the adjoining jungle. Each hole is about eight feet from the other; but the present appearance of the plants would seem to indicate this distance as being a little too close for the future full developement of the tree. The plants, after being put out, were at first slightly shaded, and watered, when there was no rain-fall, every second day. The shade and watering were afterwards gradually dispensed with, as the plants shewed signs of having established themselves firmly in the ground and when indications of their making young wood were discernible. Several of the plants are now shewing from three to four pairs of primaries and carrying in some instances leaves measuring 16" + 9." The plants are now a little over a year old, and are from 5 to 8 feet in height—the elevation of the land in which they are planted being about 800 feet above sea level, and preserving a moist, warm, and very forcing climate. One plant which was sent to another part of the country and planted under similar circumstances, but at an elevation of some 450 feet above sea level, and with a western aspect, has attained even a larger growth than those at Strathmore. But although nearly 6 feet in height, it shews a tendency to be more *lanky* and perhaps less robust or hardy looking. Another experiment was tried on an estate possessing particularly fine and friable soil, at an elevation of about 1,400 feet above sea level, and even in this instance the appearance and rapid growth of the plant are everything that could be desired. I regret, however, to observe that, even in the case of the two isolated plants just referred to this species of coffee shews no signs of possessing immunity from the dreaded leaf-disease (*Hemileia vastatrix*); but on the contrary the plants were, almost without exception, all attacked with fungus before they had been any length of time in the ground. As yet, however, it is not apparently of a very virulent type, and I hope in a future report to be able to state what effect the disease may have in the bearing capabilities of this description of coffee. In conclusion, I would suggest the extension of the cultivation of Liberian coffee in the lower ranges of the Travancore Hills, where the ordinary description of coffee cannot be successfully cultivated owing to the protracted drought during the early months of the year; and am of opinion that both soil and climate are well suited for its proving a remunerative speculation." It was resolved, that Mr. Grant and Mr. Anderson be thanked for their Report and informed that the Society will be glad to have further reports, as to the success of this important experiment.

The Honorary Secretary reports that one of the Liberian coffee plants received from Kew on 17th July 1877, and planted out in the open in the experimental garden, on 25th February 1878, produced ten blossoms on the 14th December last, and seems to be in good health and likely to mature its fruits; also that another planted in the shade has several buds upon it; and that the flowers are so large and beautiful that he thinks the plant worth growing for them if not for its fruit.

AGRICULTURE FOR PLANTERS.

BY A. C. DIXON F.C.S., M.R.A.G.S., B SC. & SCI. M.B., (London.)

Continued from page 105.

ALTHOUGH cattle manure is most valuable yet its supply is no equal to the demand, nor will there be but a very limited quantity until more attent ion is devoted to the growth of fodder crops for con version into flesh and manure. There is a considerable demand for animal food, and the profit which might be derived from the sale of cattle reared with that object, together with the manure yielded would amply repay cost. As matters stand at present cattle manure is bulky and produced mostly in the low country: this coupled with costly transport stands in the way of such free use of this manure as would otherwise be the case, therefore the only way to meet the difficulty would be to grow large quantities of fodder in connection with estates,—and further, I do not advocate the use of fat meat in the warmer parts of the island, but for those who really prefer such, it could be produced up country. Fattening cattle down here is not natural, and if such practice be pursued, we may then look forward for a whole train of cattle diseases.

I gave the amount of nitrogen or in other terms ammonia, that occurred in cattle dung, but planters must not run away with the idea that it is the vital part. I put it in such form as cultivators are accustomed to look for it. It is not the nitrogen or its successor ammonia that has the lasting effect which farmyard manure gives, but the varied mixture of incombustible ingredients.

I am rather inclined to think that too free a use of nitrogenous manures may have something to do with the leaf-disease. It seems to be need ful at the present day to add something of this sort to mixed manures or they cannot be sold. I do not wish it to be understood that no value is to be attributed to such, but it is small compared with other portions. These bulky and decomposable manures play a very important part in causing the ground to be opened, and to keep it open by their decomposition.

If all countries intend employing the quantity of nitrogenous matter or ammonia, as is done in England, where can we find a supply? Another most valuable manure is birds' droppings or *guano*—this term is applied to the more or less decomposed excrements of sea birds which

live upon fish, and have congregated for ages in myriads on many of the islands of the southern seas, and have formed immense deposits of their excrement, together with feathers and dead birds. These guanos are of two chief kinds, the one chiefly phosphatic, containing a small percentage of ammonia from ·5 to 1, but a high per centage of phosphates, often from sixty to seventy-five per cent., the other rich in nitrogenous matter. Both these guanos have a common origin, the one has lost its nitrogen, which has been converted into nitric acid and so washed out, leaving the phosphate behind, while the other has not been subjected to such wash, as for instance Peruvian Guano which has a good proportion of nitrogen as well as phosphate: this is due to the absence of rain in the country.

This manure is of too stimulating a nature to be useful for coffee: it is just the thing for giving vegetation a start at a certain period of its life, especially those plants which are short lived; its action is similar to a fly wheel in an engine, it carries the plant over certain dead or sluggish periods of its existence. Its affect also is short lived. It might be used for mixing with non-stimulating manures, but it is not good alone, neither would cattle dung were it collected and stored for long periods in the same manner.

We have yet another guano of very great value, but like the last, too strong to use alone, and that is from, *Bats*. Large quantities of such guano are found in Arkansas, Texas, Southern Spain, Jamaica, and several of the East Indian Islands. It consists of the dung and dead bodies of bats with earthy matter, and is found in caves which innumerable bats have frequented for ages. Some of these guanos contain up to ten per cent. of ammonia, and of phosphate of calcium from thirty to forty per cent.

A somewhat poor sample of bats' guano from Penang was analysed some short time ago, which analysis I now give.

Moisture	10 5
Organic matter	9·3
Phosphate of lime	38 0
Carbonate of lime	5·7
Sulphate of lime	13·8
Magnesia	0·7
Potash	6·0
Siliceous matter	16·0

The organic matter in this was equivalent to four per cent. of ammonia. This manure is much valued by planters in that locality. I have no doubt that caves occur in Ceylon which have been frequented by bats attracted by the great number of insects, for long periods of time and in which great quantities of valuable manure are stored. I think one region is called the Nitre Cave, here the dung from the bat has yielded nitric acid which uniting with the calcium, occurring in such caves has yielded nitrate of calcium. This like bird guano, might be advantageously mixed with others. We will next consider *poudrette* or human excrement, which is of great value and might be utilized to a much larger extent than is at present the case.

Poudrette as sold, however, contains a good proportion of useless and a very small quantity of excrementitious matter, often containing only three per cent. of phosphorus, and about the same of ammonia.

As far as poudrette is concerned, we might well take a lesson from the Chinese and Japanese who know nothing of the exhaustion of the soil, whose fields have yielded in abundance for thousands of years and this is accomplished by the use of poudrette. Human excrement there is highly valued. Every care is taken of it, it forms one of the chief articles of trade after grain and food. In Ceylon, excrement might be utilized to a great extent by the use of proper absorbents. The Chinese and Japanese have fully proved by their system that if the mineral matters are not restored to the soil, exhaustion must follow. The air supplies a portion of the combustible matters nitrogen and carbon to the soil, and the excrement which they return supplies the rest.

In Colombo alone if the same care were taken of excrementitious matters as is the case there, we should have an annual supply of manures containing 220 tons of phosphoric acid.

Another and exceedingly valuable manure of the animal class is bones, many tons of which are annually imported in various conditions.

The general composition of bone is

Water	6·2
Organic Matter	39·1
Calcium phosphate	48·8
Lime	2·6
Magnesia	·3
Sulphuric acid	2·7
Silica	·3

The organic matter being equivalent to 4·8 of ammonia.

Commercial bones vary very greatly; the Australian are preferred to the Indian, being richer in phosphate, and why is this? It is because the food of the animal here is less phosphatic than in Australia; and that it means the soil is not so, as many suppose. The soil here is not poor in phosphate, as has recently been stated, except in those districts where it has been removed in the shape of coffee berries for a long term of years without any return being made to the soil.

Analyses may say that phosphates are deficient, but on what grounds? probably on the analysis of the stem of a plant or tree. Can we expect such parts of plants to yield phosphates to any extent? Do phosphates enter into the composition of the hard tissues of plants as they do in animals? Can a man who knows the composition of plants, pass but briefly through most parts of this island and observe the natural vegetation, and say that Ceylon soil is singularly deficient in phosphates? I recently analysed for a planter the ash of a common estate weed and found its composition thus: it yielded 7·8 per cent of ash, and this ash contained 35 per cent. of potash and 8·5 per cent. phosphoric acid, and many other plants I have no doubt would show a fair proportion of these components.

Bones before being applied to the ground are subjected to various modes of treatment which affect their value.

They contain other valuable ingredients beyond phosphates. They are often boiled in order to extract the fatty matters which are utilized for soap making; this removal of fat accelerates the decay of the bone as such matter prevents the free access of air and moisture.

Boiled bones are the best for conversion into superphosphate, as the sulphuric acid with which they are treated acts upon the carbonaceous matter which surrounds the particles of bone and so prevents its full action.

Again after the removal of the fatty matter bones are often accumulated in heaps, whereby the decomposition of the nitrogenous matter they contain, great heat is developed; they soften considerably and can then be pulverized with greater ease; lastly they may be subjected to the action of superheated steam in order to extract glycerine and similar matters which are much used for stiffening various fabrics, the bones are however, still valuable on account of phosphates which are not removed by such processes.

To get the full effect from bones they should be pulverized well, without having undergone these boiling processes. The pulverizing may be greatly aided by steaming the bones provided care is taken not to allow various matters, resulting from such, to escape into the air, they can be absorbed by coffee dust, or the ashes resulting from the burning of chaff, &c.

Bones applied to the soil in such form contain the normal or tricalcic phosphate, an insoluble compound in water yet sufficiently soluble when in the soil for the purposes of the plant.

Superphosphates are well adapted for several rotation crops but not well suited for coffee, as they have too great a tendency to force the plant.

What is superphosphate is a question often asked. As I said before, the phosphates are somewhat difficult to understand. The normal phosphate of calcium as found in bones, is the tricalcic, it contains 3 atoms of calcium, this is the most insoluble form. By treating this with sulphuric acid two of the three atoms of calcium: unite with the acid to form sulphate of calcium or gypsum, while the two atoms so removed are replaced by hydrogen so forming a monocalcic phosphate, sometimes called biphosphate, a much more soluble form.

The manufacture of superphosphate is carried on in England to a very large extent; there are at present about a dozen firms who produce from 45 to 50,000 tons annually, as well as smaller firms making from 10 to 20,000 tons a year. The quantity of phosphatic material imported to supply the demand for artificial manures is about half a million tons annually.

Fish manure is one of great importance to the planter. It is one of the chief sources of phosphoric acid as well as of lime, various alkaline salts and nitrogenous matter. The hard parts of fish are similar in composition to the ordinary bones of commerce. Those of the bird hold the first place with respect to their richness in phosphoric acid. Next in order we have the bones of mammals, and then fish. The relative value of these are nearly in the same ratio as the numbers 16, 15 and 14. The softer parts of fish contain a considerable amount of phosphorous, which by slow oxidation is gradually converted into phosphoric acid, so increasing the value of fish manure as a whole. Fish manure is capable of being largely adulterated, if care is not excercised in the process of drying, and making ready for exportation. It is usually dried on the sand, and a great quantity of this adheres to the fish during this process. In some cases the bodies of the fish are crammed with sand—and in order to ensure a large amount adhering to it, the drying grounds when they have become caked and firm are broken up. Of fish manures at present imported Massey's patent appears to contain a minimum of sand: *viz.*, under 10 per cent.

In some manures this adulterant has reached 50 per cent.

Other animal substances such as refuse from the manufacture of meat extract in Australia, carcases of dead animals, blood, hair, &c., are occasionally used for manure chiefly composted with earthy matter, in order to retain the gases of decomposition.

VEGETABLE MANURES.—Green manuring as applied in England is inadmissable here, since the crop is permanent, it is done, however, in a certain sense as when the weeds around the trees are buried in holes or trenches: with a soil to a good depth and friable it would be better to return them in the form of compost.

The pulp of the coffee although considered by some, not to be of much value, should be returned to the soil, as its elements will always furnish material for fresh supply. The matter of which it is composed is not woody fibre, and therefore soon decays: it also contains a great quantity of sacchhrine matter which is valuable as a source of carbon.

POONAC or Oakes of various descriptions, in a pulverised or crushed condition, have a very beneficial influence on the soil. The are composed of seeds of various kinds, *minus* the oil that has been more or less extracted from them. They all contain valuable ash constituents, as well as nitrogenous and carbonaceous matter.

These cakes resulting from the seeds of various botanical families having different habits of growth and requiring different substances for the formation of their seeds, are of various relative value.

It is difficult to give them in order as valuable for manurial purposes since they vary considerably, however, it would generally be as follows: China bean cake would take the first place, followed by decorticated cotton, rape, gingelly, linseed, black castor, cocoanut and dombo.

The ash of some of these cakes contains over 1½ per cent of potash, and about 5 per cent of phosphate of calcium.

The nitrogenous matters of some are slightly soluble, but become more so, by decomposition, and are then more readily diffused through the soil than those from many other manures, consequently, it is not long before their effect is evident. Their chief action is the formation of wood and foliage.

MINERAL MANURES.—Of these, we have a great number, each capable of doing its particular work for the soil, or for the plant. One of the chief of these, is *lime*. It occurs naturally in Ceylon, mostly as carbonate, and is found in great quantity in the northern part of the island. Along the coast, as coral and shells (shells especially on the pearl banks, where great accumulations have taken place, and which might well be utilized) and in the interior as masses of crystalline dolomitic limestone of a mottled grey appearance, sometimes nearly white. One specimen which I have analysed contained 70 per cent. of carbonate of lime, and 15 of carbonate of magnesia.

Carbonate of lime is useful to most plants, since it is readily soluble in rain water. It would be best applied in the form of ground coral, for the crystalline limestone and shells would not be so easily crushed.

It is of great value on stiff heavy soils, acting mechanically, as well as chemically, on the latent stores of food in the soil, liberating the alkalies.

Lime is essential for the healthy growth of agricultural produce, without it, many crops are subject to diseases, and roots sometimes fail altogether even if they have been liberally manured with cattle dung.

Its presence has a great influence on the change which soluble phosphates or manures containing these, undergo in contact with the soil, On all soils deficent in lime, manures rich in soluble phosphate do not produce such a beneficial effect as upon soil containing even a small proportion of lime.

Lime is often applied not in the form of carbonate, but as an oxide. The oxide is readily prepared by subjecting any of the various forms of carbonate to the action of heat in a kiln, driving away the carbonic acid gas into the air not to be lost, but to return again in some form or other, it may be to harden the mortar with which we build our houses.

For building purposes we burn the carbonate, reduce it to oxide, mix with water and sand then place between the bricks of cabook or stone for what? To take back a similar amount of carbonic acid gas as was driven from it by burning in order to harden it, and this gas it obtains from the air. In the same way the burnt lime applied to the soil or to the compost heap will rapidly take up moisture and after that carbonic acid returning to its original form, but in a more finely divided state. In its burnt state it is highly caustic and well suited for decomposition of vegetable matter hence its suitability in a boggy or sour soil, Its great work is to aid the plant in obtaining its food by its mechanical and chemical properties. Lime may also be applied in other forms—for example, we may employ the sulphate commonly called gypsum, such is not found in quantity in the island, and its use will therefore be limited until we have a sulphuric acid manufactory.

This compound of lime is of great value for fixing ammonia resulting from decomposition of various manures, as well as for promoting the distribution of the alkalies in the soil. It occurs in all superphosphates being one of the by-products in its manufacture which is not separated.

We have also gas lime of a very caustic nature suitable for keeping weeds in check, and for aiding decomposition.

In addition to lime it contains various impurities of coal gas, such as sulphur compounds and hydro-carbons. The quantity obtainable is however, very limited.

Mineral phosphate of lime as coprolites which are the fossil excrements of the great reptiles of former ages, occur in some of the geological formations in various parts of the world, large quantities of these are subjected to the action of sulphuric acid, and converted into mineral superphosphate which is almost on a par with that derived from bones, as far as phosphate is concerned.

The general percentage of phosphoric acid in English coprolities is 56 per cent. Sombrero phosohate occurs in the island of that name in the West Indies, and is valuable as a source of mineral phosphate of time. The island appears to be composed of this earthy matter, it is thought to be fossil guano.

ALKALINE SALTS.—Potash is a very important element for coffee, but the soil here is generally very rich in that element containing almost an inexhaustible supply, provided the soil is cultivated to a good depth so as to admit of the latent potash now in the form of silicate to be decomposed, but where such is not the case it will be advisible to return potash in the form of manure, but not of such a stimulating character, as some of the potash salts, for example the nitrates.

There is a valuable combination of alkaline salts which has already found its way to Ceylon, the kainite and strassfurth crude potash salts obtained from Germany. These are used with much advantage in compost heaps to accelerate decomposition and fix volatile matters.

The composition of this salt as analysed by Dr. Voelcker, is :—

Moisture, loss at 212° F.	3·36
Water of combination	10·88
Potassium sulphate	24·48
Calcium sulphate	2·72
Magnesium sulphate	13·22
Magnesium chloride	14·38
Sodium chloride	30·35
Insoluble siliceous matter	·71

The sulphate and chloride of ammonia are salts useful for mixing with other manures, they are too forcing to be used alone, they render the earthy phosphates soluble, Common salt has a similar property.

Wood ashes are valuable as a source of alkaline matters, more especially potash which they yield in the form of chloride and carbonate. They are of greater value if the wood, &c., has not been fully burnt, leaving a quantity of charcoal useful for absorbing gases. Ashes should always be mixed with earth in order to prevent the waste of alkaline matter by wash.

Composts may be of all kinds according to the varying ideas of the planter. All animal and vegetable matters should be utilized in this way, different substances may be applied to the heap as ashes, cattle dung or other refuse to form a general manure. He must guard against adding burnt lime to substances rich in ammonia. In conclusion, I may remind the planter that the great components of his manures should be *phosphoric* acid, *potash* and *nitrogen*. These are what he has to obtain in order to feed his plants that they may make a fair return for the labour bestowed upon them. He may purchase these separately, and form his own special manure, or he may buy them already mixed, taking care that the value is regulated by the quantity of essential ingredients at a certain price per unit.

TOBACCO.

TOBACCO CULTIVATION.

(From the Madras Athenæum.)

WE want educated young men to cultivate tobacco. Good American seeds can be obtained from the Sydapet Farm and if ten acres of land were cultivated with tobacco, we are sure that the profits accruing from those ten acres will be considerably larger than the monthly salaries of clerks in public offices. Mr. E. Buck, Director of Agriculture in the North-West Provinces, says that an acre of land properly cultivated with tobacco yields a profit of Rs. 167.

An acre of land if properly cultivated will yield 800 lbs. of tobacco. In Maryland the average yield is 1,000 lbs. According to Warden "a hogshead weighing 1,350 lbs. is considered a good crop. On the fresh rich lands of Kentucky, from 1,000 to

1,500 lbs. are raised per acre." We see from this that an acre of land may produce more than 800 lbs.; but we think we are safe if we take 800 lbs. as the average produce for an acre. Mr. Buck too adopts this calculation. The price of one lb. in the English Market is *5d.* The following figures indicate, according to Mr. Buck's calculation, the profits which may be derived from the cultivation with tobacco of ten acres of land.

10 acres at 800 lbs. an acre.

For cultivation at Rs. 4 per maund of 80 lbs.	... Rs.	400
For curing at " 5 " " " 80 "	... "	500
For export at 8 pice a lb. about ...	... "	330
Profit	... "	430
Total 10 × 800 × *5d.*	... Rs.	1,660

It will thus be seen from the above, that if an educated man took some ten acres of land fit for tobacco cultivation, (and we are sure that the nature of the soil in Southern India is suitable for tobacco cultivation) and cultivated the same properly, he will get a profit of Rs. 430 or more than Rs. 35 a month, besides the profit that will accrue to him by the sale of the second growth plants which spring up after the first cutting, and which yield on an average, about 5 maunds or 400 lbs. an acre. It is thus clear that the proper cultivation of ten acres of land with tobacco, will give the cultivator about Rs. 45 a month; and this Rs. 45 a month, in an independent line, is immensely superior to Rs. 20 or Rs. 25 a month in a public office. Let the educated men of this Presidency consider our suggestion and see if it is not one that ought to engage their attention. Many suggestions of a similar nature could be made, but for the present we shall rest satisfied with this one. A word in conclusion with regard to the saving of tobacco seed. This is done by attention being paid to the following direction:—"Allow a few of the strongest plants to produce their flowers; they will have a fine appearance in July and August, and in favourable season each plant will ripen as much seed in September as will sow a quarter of an acre."

On the same subject the *Rangoon Weekly Review* has the following remarks:—It is estimated the outturn in good tobacco leaf from a properly cultivated acre of land ought not to be less than 800 lbs. In America the average is reported to be usually 1,000 lbs. East Indian tobacco generally sells in London for *1d.* or *2d.*, and excellent varieties fetch about *5d.* per lb. The Myouk-toung tobacco is so favorably spoken of that we may with some safety expect the latter price for it. Then if the Government farm there consists of 200 acres (this was its proposed extent) 800 × 200 × 5=800,000*d.*, or Rs. 33,333 per acre or Rs. 2,777-12 per month. Not an unprofitable speculation. Native calculations, however, give 370 lbs. as the average yield of an acre under tobacco cultivation. The calculations then would be 370 × 200 × 5=370,000*d.*, or Rs. 15,417 per acre or about Rs. 1,285 per month, even this is not bad. It is probable however, that the native growth would not fetch so much as *5d.* per lb. But in the Government farm at Ghazipore, and in Bengal farms, 800 lbs. have been readily obtained, and there is no reason why the superior soil and situation of Myouk-toung should not yield as much under proper care and scientific cultivation.

II.

It is with pleasure we notice the local administration persevere in the matter of improving the cultivation and curing of tobacco if the country is to advance more its natural products must be attended to in greater degree than has been the case; and of all vegetable productions there is none which the country promises to succeed so well in as tobacco. The plant grows in all parts—on the *churs* created by the rivers, as well as on the hills. In Northern Arakan it is found in the same district both on high lands and low lands, and all over the province this is the case. As far as quality is concerned, the best experts have pronounced it to be equal to any of the American grown, Manilla or Havanna kinds. The Kyouk-kyee tobacco is admirably suited for the manufacture of Cavandish or plug-tobacco.

It wil be within the memory of most readers that about 1876 the local Government made a decided move in this direction. The services of the late Dr. E. Brown were obtained on loan from the Government of Bengal, and the worthy doctor, leaving Ulya in the latter end of 1875, landed here in the early part of 1876. He was then despatched to Thayetmyo, Shwegyeen and Arakan. It is a pity his tour of inspection and report was not better planned; for the time was so ill chosen that wherever he went he could do little better than analyse soils, and report on growing crops. The country thus lost practical demonstration from an experienced person of how to effect the proper cure of the leaf. In Thayetmyo he was too early—the plants were growing and would not be fit to cut for months. So it was in Shwegyeen. In Arakan, if we mistake not, he was also too late. Had he been sent to the place put down last, first, results would, in all probability have been different. But, however much it is to be regretted no practical lessons in curing were given to the people, it will always be matter for congratulation, such an officer's services were secured, for now the capacity of the province for growing the plant has been established beyond doubt.

Tobacco growing and cure differ in districts owing not so much to difference in soil and climate as to local habit and prejudice. In one place the plant may be seen on low-lands which the river-floods have left and where the trouble for preparing the land is least; in another more care is taken in this direction. In some parts the leaf is shed green and dried, producing a strong tobacco, as on the Shan hills of Kyouk-kyee; in another the entire plant is strung up to dry over the kitchen, the produce being a mild flavored one. But the soil in most districts is rich and suited to the plant, that on the Arakan Hills producing the best kinds grown. The leaf from Sandoway, Cheduba Ramree, however, is small and woody and ill-suited either for export or the local manufacture of cigars. What the people require instruction in is to grow the plant properly and so cure the leaf as to develop the proper aroma. As at present carried out the cultivation is indolently and carelessly done. When seed-sowing is done the natives fancy all that is necessary is over, and no care is given to see the plants mature. In some places tobacco is grown with paddy, and when the sickle is put to the latter, the former is plucked up, taken home, hung up to dry, and consumed as required. The soil and climate are so favorable that almost invariably a good crop is secured. In the eastern parts the taking up of the crop is done before the rains, the hottest season of the year, it is therefore not to be wondered the drying ruins the leaf. The natives need to be taught to grow the plant *through the rains on the high lands*, and cure the leaf during the comparatively moist months of November, December and January, and, whomever the Government may appoint, it is to be hoped his attention will not be confined to work only within the fence of the Myouk-toung farm.

Myouk-toung itself is the best place for growing tobacco, and therefore the best situation for a farm such as the Government has. It enjoys special advantages, being close to the embrouchure of the Pee and Mee rivers, confluents of the Koladan. Labour is available from a Shan colony at hand, the soil is rich, and the climate all that can be desired. Carriage to Akyab, from which the place is distant about 71 miles, is easy on account of the river, and the prospects are the Government farm here will, if properly managed, open out a source of revenue and most likely one of wealth and prosperity to the country. The main object of this institution ought to be the imparting of a knowledge of cultivation and curing. To do this effectually natives willing to learn should be admitted as farm-hands; any native wishing to become acquainted with the methods pursued should also be informed; and the place thrown open to *bonâ fide* cultivators and tobacco-growers at all times. There is no reason why the place should not become a centre for the radiation of better ideas and improved methods of cultivation, and on appointing a Superintendent, it is to be hoped this improtant point will be prominently brought forward and impressed. The time, however, is short, for if anything appreciable is to be done, it must be done by July the latest.—*Rangoon Paper.*

CINCHONA.

The alarmingly increasing rate at which the cinchona trees of Peru are being rapidly exterminated has at last led the Government of the Republic to take legislative measures for the suppression of the evil. Gathering the bark will be permitted as heretofore in all departments of the Republic, except only in the Sandia and Tambopata valleys of the province of Sandia, where the *Cinchona lancefolia*, from which the so-called "calisaya" quinine is obtained, chiefly grows. But felling the trees is absolutely prohibited throughout the whole country, and the bark-stripping is henceforth to be conducted only under certain stringent conditions as to manner and time. To guard against possible contingencies, it is ordered that, in case of need, the Prefect of Purio, in which department the above-named valleys are situated, is authorized to place them under military control.

CINCHONA CULTURE: HOW TO SAVE THE LABOUR AND EXPENSE OF "PRICKING OUT" SEEDLINGS.

MR. HENRY POET writes from Rambodа to the *Ceylon Observer*:—Ever since I had anything to do with cinchona, it has struck me that the system in vogue for rearing plants is at fault. I have an idea, and that idea I will, with your permission, ventilate through my old friend the *Observer*. The usual course adopted, as you are aware, is to plant seed broadcast in covered beds, and afterwards, when the young seedlings have attained a certain size, to "prick them out" into beds which are also covered. This method entails a heavy expense.

Now what I am doing is this: I first make a quantity of beds, 3 feet broad and any length you like; these beds are divided from each other by drains 15 inches broad and 12 inches deep. The soil removed in the making of the drains is thrown on the centre of the beds and drawn down on either side so as to give the beds a "barrel." Over this I place a dressing of sand and mould ½ inch thick, in the proportion of 3 of mould to 1 of sand. Over this again I place a very fine dressing of sifted river sand: I mean the very finest small-grained sand you can procure. The object of this you will see anon.

The beds are now ready for receiving the seed. The manner of sowing is this—mix your seed with forty times its bulk of sifted earth. This part of the process is simple, but requires patience and accuracy. Take a tumblerful of the earth and place it in a box; on this put a tumblerful of seed, and thoroughly mix the two—then put into this another tumbler of earth and again mix intimately, and so on till you have 40 tumblers of earth thoroughly blended with the one of seed, continuing this process till you have all the seed you wish to plant so treated. This mixture of 40 to 1 of earth and seed is then to be *very thinly* scattered over the beds, and the thin coating of white sand will render it easy to see that this is evenly done. In my opinion if this be carefully done you will by this method do away entirely with the necessity for "pricking out," and thus save largely in time and outlay.

REPORT ON THE GOVERNMENT CINCHONA ENTERPRISE IN JAVA FOR THE 4TH QUARTER, 1878.

(*Translated for the Ceylon Observer.*)

THE weather during the past quarter was very favourable for operations. The rains began in the very first days of November, and have continued steadily since. In the last part of December strong winds did some damage, especially on the Nagrak and Kendeng Patuha establishments, where the buildings suffered much, and some hundreds of cinchonas were uprooted or broken.

Nine thousand nine hundred and ten days' work was performed by temporary hired labour. A great number of the plants in the nursery beds were able to be put out: they comprised 47,310 *ledgerianas*, 43,485 *officinalis*, and 21,550 *succirubras*. Their planting out was favoured by the most desirable weather, and the young plants are progressing exceeding well.

The gathering had to be discontinued at the beginning of November, when the rains commenced. Altogether there were gathered 121,343 Amsterdam pounds of bark, of which 112,321 Amsterdam pounds were reserved for exportation to Europe, whilst 9,022 Amsterdam pounds were kept for the use of the military medical department here.

The despatch went on very slowly during the last month, as the draught cattle, which are usually hired from the natives, are now required for working at the sawahs.

The distribution of *C. calisaya ledgeriana* seed has gone on steadily. The blossoming of the *ledgerianas* is beginning later than in the previous years, since scarcely any buds at present are visible. The seed will therefore also be ripe later, and in 1879 will probably not be ready for distribution before November and December.

The results of the chemical analyses are given in the annexed statement. The experiments with the partial stripping (mossing system) were continued, and from the analyses 161-175 it is clearly seen how the composition of the new formed *succirubra* bark differs from the original. The value of the bark is much greater, since by renewing the percentage of quinine is almost trebled. In the case of *succirubra* this is manifest; the renewed barks of other sorts were yet too young for a definite conclusion to be arrived at as to the change caused in them by the mossing system.

The original bark also, which has been a year under moss, improves by that means the amount of valuable alkaloids.

The analyses 71-76 deserve special attention. They are from 4-years-old *ledgeriana* seedlings. The plants which resemble the mother-tree least (75 and 76) had also a bark of inferior quality, whilst the bark of those which approached nearest to the type of the mother-tree showed a percentage of quinine which for such young plants is already very high. The chemical analyses will especially in this direction be proceeded with, in order to obtain as speedily as possible certainty with regard to the question, how far *ledgeriana* seed plants agree in yield of alkaloid with the mother-plants from which they are derived.

CONTENTS:

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.

LETTERS TO THE EDITOR.

RIDLEY'S REAPING MACHINE.

Sir,—In the *Agriculturist* of October last, page 341, in a article headed "Wheat Cultivation in Madras and Australia," I find the following passage :—

"The expense of cultivation (in Australia) is small and the gathering in of the crop when it is fully ripe costs a mere trifle, *thanks to Ridley's Reaping Machine*, which reaps and thrashes the wheat by one simple process.

This machine merely clips off the ears of the wheat, and leaves the straw standing on the ground."

Would any of your readers kindly let me know where this Ridley's Reaping Machine is manufactured and sold,

S. DATTA.

Bishwanath.

Note.—Mr. H M Rogers (late B C. S.) 20, Corn Exchange Buildings, London, will furnish our correspondent with information on the subject.—Ed. *I. A.*

ELEVATING THE MAHAJAN.

Sir,—It is acknowledged that the low class of tillage so universal in India, is incapable of improvement with the amount of capital devoted to it. It is the maximum result obtainable from a minimum of expense. If we could induce capitalists to move money into agricultural works, there is no doubt that the return would justify the expense incurred. Thus with a stronger class of bullocks, an improved plough could be sent through the soil and new layers of mould brought to the surface. With small outlay improved water lifts might be made that would permit double the land being watered at no high cost. With a greater expenditure of manure, the same area of land would yield richer crops, and increase the surplus for export. Can we bring these facts home to the village sowcar, so as to induce him to lend capital to men who would devote it to these improvements? Here and there in the country we have experimental farms, where these innovations are adopted, but they are too few to effect much good. Yearly increased numbers of iron ploughs, and improved water lifts are being sent out from them to purchasers in different parts of the country, and in the district of Coimbatore the Double Mhote for raising water is fast superseding machines which though costing less in the first instance, are in the long run less effective. The desire for greater agricultural knowledge than can be obtained generally in the districts of India, is manifested by the number of applications for admission from a variety of classes and castes into the Technical Agricultural School at Sydapet—applications far in excess of the room and instruction available. We have in these examples, evidence that a desire exists for Agricultural knowledge with a view to improve India's future prosperity, and Government should use every endeavour to attract the attention of the monied classes, *more*, especially the village sowcars, to the subject.

THE PURCHASE OF COFFEE LANDS IN COORG.

Sir,—It will be interesting to the planting portion of your subscribers as well as a warning to intending purchasers of coffee lands *from Government* in Coorg to be informed of the following facts :—

In the month of September 1876 after some years of waiting and delay caused by the indolence and indifference of the Coorg Forest and Revenue Department, I became the purchaser at an auction sale under the waste land rules of the Theewar-betta jungle for Rs. 13,050 and which was stated in a specification published in the *Mysore and Coorg Gazette* to contain acres 185-16,

On the 4th of October following I also became the purchaser from the Coorg Government under the waste land rules of the Maymotti jungle adjoining the one I had just purchased and for this second purchase I paid the sum of Rs. 2,206 the land being represented by specification similarly published as the former to contain 20-10 acres.

I may here observe that my first purchase averaged Rs. 70-8-11 per acre, and my second Rs. 110-9-9 per acre, being some Rs. 40 and 80 more than has ever been paid in Coorg before or since for the purchase of land under the waste land rules.

In May 1878 and after incessant and urgent applications my managing superintendent (nearly two years after the sales) obtained from Government the survey plans, and upon an examination of them with the land, discovered that the area of my second purchase (the Maymotti jungle) was included in my first purchase (the Theewar-betta jungle) and that instead of my two purchases aggregating 205-26 acres as misrepresented to the public by Government, (I presume not wilfully) they only aggregated together 185-16 acres or the area of my first purchase.

By the date of this discovery myself and my partner (Mr. C. M. Grant) had expended on the cleaning and cultivation of the land with coffee and cinchona some Rs. 30,000 in excess of the amount paid to Government.

We not unnaturally concluded that we were entitled to a refund of the money paid by us for the second mistaken purchase, and I accordingly represented the matter to the superintendent of Coorg, and applied that the money namely Rs. 2,206, we had paid by mistake and which was at the same time conceded they had taken in equal good faith, should be returned to us.

As I happened to be on the spot at the time my personal representation was favourably enough received and the matter was at once referred to the 1st assistant superintendent of Revenue Survey, who with characteristic promptitude confirmed my statement that I had paid twice over for my Maymotti land or second purchase, or what was the same thing that officer reported that it had been surveyed twice over being already included in my first purchase, the Theewar-betta land.

We were then promised a refund of the amount improperly demanded and paid by mistake, but at the same time informed "*certain formalities*" would have to be gone through with the Accountant General at Bangalore. This occurred so far back as April last year, and although myself, my partner and our manager Mr. J. . Gerrard, have since been continually urging a speedy settlement it is only on the 17th of March instant, that we have received an intimation that "the Chief Commissioner regrets that he is unable to grant the refund *solicited*."

I will not trust myself to comment at any length upon the action of the Coorg Government (and I challenge a contradiction of the facts above stated) but I cannot forbear remarking upon the hardship to which myself and my partner are subject in being put to the expense, delay, and anxiety necessitated by probably prolonged legal proceedings in a remote *non-regulation* Province and in a Court where the presiding judge is the *head revenue officer* to recover (with what little hope of success you may imagine) money appropriated under circumstances that I am advised had our vendor been a *private individual* instead of a *Local Government* might properly have been made the subject of a criminal prosecution under the Indian Penal Code.

In conclusion for the present I may be permitted to remark that the foregoing will give your readers an opportunity of remarking what reliance is to be placed in the repeated asseverations of Government that they are wishful to foster the planting interest and invite the investment of European capital in India.

A. COOPER ABBS.

Madras, 26th March 1879.

KOTEGHUR NOTES.

SIR,—The weather during this month has been satisfactory We have had fine growing showers, and though there has been some hail, yet coming at this season it has done hardly any harm as the ears of the cereals are only just forming and where they have been injured there is still time for them to recover themselves or for new shoots to come out; the real danger from hail is when it comes during the months of April-May when the barley is just ready for harvesting, in which event the grain is knocked out of the ears and strewn on the ground to the loss of the cultivator, the wheat also then suffers, as although a month behind barley in the time of ripening, still it has then reached that stage when injury to it precludes any chance of its making fresh efforts at reproducing itself. The same remarks apply to the fruit blossoms. There is a heavy storm now raging, the hail is rattling on the roof, the wind is roaring round the house, the trees are groaning, the thunder is growling, and the lightening flashing, and altogether a very tolerable imitation of a cyclone is going on out of doors.

The following is a comparative table of the past five seasons :—

	1875.	1876	1877	1878	1879.
Snowy days ...	...	2.	1	...	8
Haily „ ...	...	...	8	1	4
Rainy „ ...	1	7	9	2	8
	Dry.	Seasonable weather.	Cold, vegetation retarded.	Mild and dry.	Fine, growing.

Wind in the early part North, then veered to N.-E., afterwards to S. When the wind is in the N. quarters it generally brings rain; I presume from the fact that, passing over the snowy range it displaces the hot air of the plains causing a vacuum, which, collecting the moisture floating about in the air causes condensation and the falling of the moisture as rain. There has been plenty of thunder and lightening, moderate in sound and intensity.

The thermometer (Fht.), hung in an open verandah, W. aspect is about 47° in the morning, 53° in the evening, lowest 39°, highest 64°.

The natives have a saying that if the weather has been dry up to the 14th February and continues dry all that day, that the winter will be a late one, and will be extended into the summer. It was dry on that day, and for about five months previously, and there appears every probability of the saying proving true this year.

The male cones of the keil (*Cedrus deodora*) are out; the chil (*Pinus longifolia*) and rai (*Pinus excelsa*) are putting forth their new leaves, the shegul (wild pear) is putting forth its leaves and coming into blossom the two operations being almost simultaneous; the Himalayan honey suckle (vern. *khunti, zbang*) poplar, bird-cherry and walnut are coming into leaf; the rhododendrons (vern. *bras*) both the pink-coloured and scarlet coloured ones are out in all their magnificence the cotinus-leaved viburnum (vern. *tus-tus*) is coming into leaf and flower, violets are out in great profusion, though only a few of them—the darker kinds, those growing in moist shady places—are scented; the village children gather large quantities of them and sell them to native dealers who boil them and convert them into a syrup which is reckoned cooling and is specially used in the hot weather: the juice of the leaves is an antidote for snake bite. then there is a sweet smelling flower resembling heliotrope, the corn-tulip (vern. *ghelu*) now abounds in the corn-fields, its pretty pink and white petals making a charming contrast to the green wheat. Weeds are coming up in great profusion, specially the dock (vern. *marela*) which is a special curse of the fields and requires constant digging out to keep it under. Dandelions are out in plenty, as also the buttercup.

The woodcock has left us and migrated to the plains; martins are now preparing their nests. minahs are plentiful. For true sportsmen this is the end of the season's shooting, as the birds are mating, building their nests, and arranging for the forthcoming hatching operations. Strange to say next month and until October the hills will swarm with cockney-sportsmen who will march about with extensive batteries, killing any and every bird (especially those sitting in their nests, as they are "such nice easy pot shots.") that comes within range of their bullets, while they make one quite nervous to see the reckless way in which they fire off their shooting irons; though the chief danger is (1) to themselves (2) to any one standing behind them. The native *Shikaries* make capital out of such people and lead—or rather mislead—them into all sorts of impossible places under pretence of "showing them a thing or two" in the shape of coveys of bird or herds of animals, which turn out to be so much moonshine—and expense for nothing: when found fault with the *shikaries* give the stereotyped answer "wonderful, never knew this place to fail me before always full last year *Harris Sahib*" (evidently a relative of Mrs. Harris) "killed enormous quantities here and was so pleased with me for bringing him here that he made me a handsome present" &c., &c., all of which our worthy cockney swallows and————s, I mean blesses, his own ill-luck. Spiders, lizards, fish-worms are out much earlier owing to the mildness of the season. Bees are swarming about the fruit blossoms in great numbers.

Food grains are slightly dearer than last month, as this is an opportunity not to be lost by our richer Zemindars, so many of whom are Government officials with power to abuse their position, especially when they are under the immediate protection of the Government European servant of the district: the poor are thus ground down under official sanction. Villagers are ploughing and preparing some of their fields to sow upland-rice, millets (vern. *koda* and *kâoni*), a species of dâll called *bharrd*, and hill-potatoes (vern *gwian, pahari âlu*) our pedigree, wheat was topped during the first week in the month and the green

stuff (mixed with hay) given to the cattle who liked it much; this week it is forming new ears and in no way behind the hill wheat, growing in an adjacent field, which has not been topped.

Lentils (vern. *masúr*) are growing; the barley is well into ear; the wheat ear is also forming—the crop will be less than in former years but there will be ample to enable the cultivators to tide over until the autumn crops are reaped. Where the ground has been well and continuously manured the crops are flourishing and will yield a full return. To show how great has been the drought of the past winter I may mention that where wheat was sown late (December) last year, it has only *now* commenced to sprout, *i.e.*, after the snow that fell at the beginning of the month. The new grass is sprouting and looking delightfully green. Clover is coming into flower.

Of fruit trees there are the apricot with its red and white petals: the peach with its pink petals: the cherry and quince with their white blossoms: the apple (about a month late this year) with its delicate pink and white blossom almost as charming as a young maiden's cheeks; this year will not be a good one for apples which only come in plenty every other year; last year being a bumper season, this year will give us less, and the vine, which is just bursting into leaf.

In gardening matters all kinds of flower seeds are now being sown: pinks, the tulip crocus, and other perennials transplanted. Onions transplanted, potatoes, peas, &c., sown. Paths are being put into repair.

Koteghur,
31st March 1879.

G. P. P.

TUBE WELLS.

(*To the Editor of the "Darjeeling News."*)

SIR,—In several of your recent publications I have noticed a correspondent of your paper speaking in praiseworthy terms of the Tube Wells, but I cannot say that I thoroughly comprehend or that I understand the particular description to which he alludes. Tube Wells are no doubt beneficial in certain soils, but why your correspondent should indiscriminately recommend them as generally suited to any and every locality seems to me suspicious, inasmuch as we know from only so far back as the Abyssinian campaign that they commenced well but ended badly; if a fair conclusion is deducible from the results obtained at Zoulla Bay and subsequently further into the interior, where rocky soil was met with; when the Tubes signally failed and the Government, notwithstanding the laudable efforts on their early successes, considered it advisable to provide for a possible emergency, consequently had other resources to fall back upon, fortunately for the Army, otherwise the disastrous effects consequent on the army reaching the interior, and rocky soil, might have been a terrible check to an otherwise triumphant force. Norton's Tube Wells are doubtless good but are not equal to indiscriminate application any where and everywhere.

The Tube Wells may be likened unto the Artesian Wells, which are applicable only to localities with natural springs and to be used when such localities suit in spring and soil. It must not be thought however that I do not speak without experience of these wells and that I am not aware of exactly their capabilities. In admitting that they might be used with good results in perhaps 10 *per centum* of the gardens about the district—and this ratio is what to me seems the outside allowance—in and about the Terai there is certainly a probability of their being used pretty extensively, provided planters did not see in them more of a toy than a practical and serviceable engine, that would answer fully the requirements of the ordinary well or spring. Of course it's all very well supplying the coolies with pure water for drinking purposes, but if there were any number of wells in and around a plantation, the great unwashed would prefer to visit the *jhora* where his thirst for water would be satiated in spite of all the planter's warnings as also his appetite for a little wholesome flirtation with *kanchee* allowing that the wells—as it would be natural to suppose—were only placed within such limits as would tend to keep them from injury say in and about the coolie lines.

LIEF.

THE STERILITY OF INDIAN FIELDS.

(*To the Editor of the "Times of India."*)

SIR,—Your correspondent, "E. V. S.," in your issue of 1st March contributes a very interesting letter on the want of that sort of practical agricultural instruction which can be so beneficially imparted to the cultivator by revenue officers of every grade in their periodical progress through their districts. No doubt, the executive revenue officers of districts are in a position to suggest to the ryot many counteracting measures to prevent the growing sterility of our fields, and to enable him to render to Government the regulated tax on his produce without impoverishing himself in the attempt. Your correspondent's letter, at the same time, furnishes a good example of the indifference of all mere theorists and system-makers to the practical difficulties to be encountered in carrying out their suggestions and remedial measures. It is an instructive circumstance that no specialist or amateur has confidence in any but his own panacea for the ills of this world. "E. V. S." expresses his opinion that the true methods of profitable agriculture are (1) deep ploughing, (2) the application of manure to stimulate the soil and (3) close and incessant attention to the operations of the field, in all which, says "E. V. S.," the Indian cultivator is deficient.

As to deep ploughing, your correspondent thinks, no doubt, there are stores of fertilizing substances in the subsoil which are untouched by the superficial action of the plough. He may be correct to a certain extent, but the utility of deep ploughing has not been so decisively ascertained as is perhaps generally supposed. In the first place, we cannot be sure if the action of the sun and air would be beneficial to plants in proportion to the depth attained by their roots, if it would not be positively harmful beyond a certain depth. It would be altogether fallacious to argue that because the action of these life-giving agents is beneficial to plants to a certain depth, that therefore it would be beneficial to them to any depth. As Burke observes in one of his excellent letters, it is as unsafe a way of reasoning in physics, as it is in morals, that because a given proportion of a good thing is advantageous, that therefore the double of it will be twice as advantageous, or that it would be advantageous at all to any degree. In the same letter, written, I may mention, to Arthur Young, the distinguished promoter of agricultural science in the last century, he mentions another practical objection to deep ploughing entertained by farmers:—"The minerals, in general seem unpropitious to vegetation. Some clays seem to be of the same noxious quality, and this, if true, makes an exception to deep ploughing upon bottoms mixed with such substances, supposing the principle of deep-ploughing to be otherwise generally sound. Under this head comes the general objection of farmers against ploughing up the dead earth, or going beyond what is called the staple; that is that body of dark-coloured mould which seems to be in part formed of rotten vegetable and animal substances. All these are doubts and questions not to be passed over lightly, especially the last, because it comes from men of much experience and is not a local objection, from a particular nature of a certain substratum, but supposes an universal inaptitude in all soils, beyond a certain depth, for the purposes of vegetation." The Indian ryot, I believe, entertains the same objection to deep ploughing. Whether he is right or wrong, is a question to be decided by scientific experts on ascertained data. But to assume as an established fact in agricultural science that deep-ploughing is essential to the proper nourishment of plants, and then to reproach the ryot that his mode of ploughing is but a mere scratching of the ground, scarcely denotes a thoughtful or dispassionate mind.

As to the use of manures as stimulants of the soil, no doubt "E. V. S." gives very sensible advice. It is very good of him to advise the ryot to conserve refuse matter and utilize human fertilizers: but what does he know of the resources of the ryot in this respect? The indigenous and local manure in a village is scarcely ever sufficient in quantity for the requirements of the fields. The application of manure to any soil is, of course, intended to restore the exact quantity of inorganic substances withdrawn from that soil on each occasion. That can only be done when the produce of the village fields is entirely consumed in the village by man and animal, and the refuse of the food thus consumed by man and animal is returned to the soil in the shape of manure. As, however, there is not a village in India which does not export some portion of its produce, a large portion of the inorganic substances is thus permanently withdrawn from the soil without being ever returned to it. The cultivator must, therefore, import artificial manure to make up the quantities of fertilizing substances withdrawn from the soil. But that is a question entirely of money, and if he is unable to buy manure for his fields, that is no reason why he should be charged with being "lazy" or indifferent to his interest. The sterility of Indian fields is owing, not because the ryot does not apply manure to his soil, but because he does not possess the means to apply it in quantities sufficient to ensure the successful cultivation of his food-plants. Other countries are able to keep up the fertility of their soil because their peasantry are rich enough to supplement their own manurial resources by artificial manure imported from other places. It has been too much the fashion to represent the Indian cultivator as something of a grown-up child who is utterly incapable of minding his own interest, so much so that the manure which to him is more valuable than gold, and which is supposed to lie about and rot at his very doors, is allowed to poison his air out of sheer laziness, without being utilized for purposes of profitable agriculture, while the fact is he uses as much manure as he can obtain or conserve with all possible diligence. He is aware his soil is yearly deteriorating, and he is aware, too, that more abundant manure would restore its fertility.

"E. V. S.'s" third count against the ryot—that he *is not sufficiently attentive to his work, and is wanting in energy and application*—may be dismissed in a few words. "E. V. S." alleges no proof, worth the name, in support of his assertion, except personal knowledge of the fact. However extensive that personal knowledge may be, and however it may have been acquired, against it may be set off the experience and knowledge of our revenue servants, of those who possess an intimate acquaintance with the ways and habits of the Indian cultivator. There is no peasant in the world who works for the bare necessaries of life so incessantly, and, withal, with such cheerful resignation to his lot. With a staunch belief in a relentless fatalism, the ryot works early and late to earn that little which is left to him after the Government have rack-rented him, and the sowcar has plundered him. And be it remembered, that in spite of his hard lot in life, he rises superior to the miseries of his condition, is a loyal and contented subject, living in peace with his neighbours, and kind to the very bullock or ox that helps him to till his field.

In conclusion, I might mention that the tenor of my remarks is intended to show what *I myself* am *fully* convinced of—that under present circumstances there are no ameliorating measures the ryot can adopt which can increase, to any appreciable degree, the yield of his fields. Here and there, by costly and special appliances, the yield of Indian fields might show some perceptible increase; but, as a rule, not one of those numerous remedies so glibly suggested to counteract the sterility of Indian fields, is capable of stimulating produce to any extent. You ask the ryot to employ good seed, to use abundant manure, and to rear a better breed of cattle; but you do not reflect that neither good seed, nor abundant manure, nor a better breed of cattle, are to be obtained without money—a commodity rather scarce with the ryot. Thus it is that while population is constantly and rapidly increasing, the food-producing capacity of the soil is as certainly deteriorating, aggravating year by year the distressing condition of the cultivating classes throughout India.

5th March.

TUSSER SILK FILATURE.

(*To the Editor of the "Englishman."*)

SIR,—In your paper of the 19th current, you give credit to Captain Coussmaker for having first brought the tusser cocoon to the notice of the Government, or words to that effect, and declare that he was worthy of receiving the "Grand prize medal," &c.

Without wishing by any means to take away from the praise due to Captain Coussmaker for the time and trouble he has bestowed on the tusser cocoon, I must point out to the public that what Captain Coussmaker has been attempting to do without success had already been done long before. I allude to the rearing of the tusser caterpillars in parts of India other than where it is indigenous, and the unreeling of tusser silk from the seed cocoons.

Captain Coussmaker appears to have attempted to rear worms on leaves not generally eaten by them, and of course he failed in rearing them. Had he only studied the worm first in its jungly home, he would have learnt what to feed them on; he apparently did not do this, and used a number of leaves that others told him to use, and f[illegible]led. No one up to this has taken the trouble to discuss the matter, and what he has placed on paper stands good. He gives a list in his report to the Government of thirteen different plants on which the worms have been fed, and there are only two out of the 13 that are really fed on by the tusser worm in its jungly state. In 1862 I happened to be employed in the Palamow district, and as I had just left a firm under whom I had seen a good deal of silk reeling, the tusser worms and cocoons naturally attracted my attention. I made experiments to unreel the cocoons, and after repeated failures, in 1864-65, I found out how to work them off. I then made some skeins of silk for a friend, who sent them off to England, where it was reported on and valued by Messrs. Durra[illegible]t and Co. Unfortunately for me, this friend left the country, and as I [illegible]ad my time fully occupied with other business, I dropped the tusser cocoons. In 1868-69, I addressed a letter to the Government of India giving information as to the tusser worm, &c., and asking the Government to assist me in utilising the tusser silk, and otherwise giving it a position in the European markets; but I never had a reply to this. In 1872, I again addressed a letter to the Government of India, Agriculture and Horticulture Department (to Mr. Secretary J. Geoghegan), setting forth all I knew about the tusser cocoons, stating that I could unreel the silk from them, and proposing a scheme to open out a tusser silk filature, offering too to supply land, free of cost, for erecting the filature upon, and asking for aid, till I could place the raw tusser silk on the European markets as a recognised article of export, after wh[illegible] [illegible] would find people to take it over from the Government. I heard in answer to this [illegible] consideration. Portions of it too (I came to hear from outsiders) were printed by the Government, and sent out for the opinions of the Commissioners of Divisions. Later on I got a further reply of a negative character.

About 1873 I again took service with my previous employers in the silk business. I then found a lot of tusser cocoons at the head-quarters of my manager that had been sent to him by the Chief Commissioner of the Central Provinces for experimenting on. No one knew the process of unreeling them, so I was asked to take them in hand. I made silk from them, that I sent to the Chief Commissioner. As however the cocoons were old and considerably damaged, I asked the Chief Commissioner, Central Provinces, to send me a fresh batch; this he did, and I reeled off some more silk for him. I then had communications from the Deputy Commissioner of Chanda, and the Assistant Commissioner of Hoshiarpur, regarding the tusser cocoons and silk, and I sent them some tusser silk. Afterwards, I wrote to the Chief Commissioner, Central Provinces, proposing to open out a tusser silk filature within his jurisdiction, if he would assist me with rent-free land for the works, and grant me certain other rights and privileges; also give me the sole monopoly of reeling silk from the tusser cocoon for a series of years. In answer to this I got the following:—

No. 3371.

From—Captain W. Vertue, Deputy Commissioner, Chanda,
To—J. Deveria, Esq.

Chanda, the 14th of October 1875.

SIR,—In continuation of previous correspondence, I beg to say that I duly forwarded your letter of 1st July for the information of the Chief Commissioner, Central Provinces.

I am directed to inform you that Mr. Morris thinks the Central Provinces are too backward to offer a field for the special knowledge you possess. Mr. Morris thinks that you might perhaps find it advantageous to put yourself in communication with the Government of India, Department of Agricultural, Revenue, and Commerce, and Captain Coussmaker.

I have, &c.,
(Sd.) W. VERTUE.

I then wrote to the *Indian Statesman* stating my specialité of reeling off tusser cocoons, and asking for Captain Coussmaker's address. This letter was replied to by Captain Coussmaker, to whom I sent three skeins of tusser silk reeled off by my process, as also specimens of coloured stuffs woven in the Bancoorah district from tusser silk. These specimens were all woven with fast-dyed tusser silk. I got thanked by Captain Coussmaker for the silk I sent him. He wrote to me,—"the three skeins are the very best I have ever seen; beautifully clean, bright, glossy, and even; perfectly free from smell, and if our cocoons can be worked up like that, they must be well worth collecting." So you see, the tusser cocoons were unreeled by me in the ordinary filatures, long before it was done in Italy, and Capt. Coussmaker has brought nothing new to bear on the tusser silk question. I guarantee to make as fine silk from the tusser cocoons, as any of the Italian or French reelers. And more, my silk will have the gum on them, necessary to ensure a firm and even thread which the continental silk does not possess. Another point too is, that the silk reeled off the tusser cocoons in Europe is puffy, and from want of gum the thread unravels and shews all its fibres, very much after the appearance of the "floss" silk that is used for carpet work and embroidery purposes, and the question is whether the trade will accept of such a class of silk. If silk of this description were unreeled from the ordinary silk cocoons and sent to market, it would probably turn out unsaleable. I have found that the tusser cocoon cannot only be unreeled in filatures like the ordinary silk cocoons (with the aid of solvents), but more, they can be worked up into stuff very like cardboard, and if after the cardboard is passed and dry it had given back to it the albumen and tannin, which it lost in manipulating, the cardboard or "block silk" as I call it, resumes the peculiar hard leathery texture it originally had; I am disposed to conclude that such prepared block silk will eventually supersede gutta percha and caoutchouc (Indian rubber) to a good extent because the substance appears to me to be a non-conductor of heat and not susceptible to lose its elasticity. I have, however, not been able to carry out any extensive experiments with this prepared material. It would, however, be of the utmost importance to science and art that the properties of "block silk" should be tested, and its capabilities experimented upon. The Government ought to be able to undertake this investigation. If necessary, I will explain to the Government officials how to manufacture the "block silk" I allude to; and if required I will supply eight to nine maunds of tusser cocoons at prime cost, to carry on the experiments with. The Government somehow make no mention of my previous communications regarding the unreeling of the tusser cocoons, and Captain Coussmaker also does not, in his publications seen by me, make any mention of the specialité I have worked out. Be this as it may, there is a great deal [illegible] before the tusser [illegible] understood; and

it is to be hoped that the Government will spare no cost or trouble to do the needful in the matter.

In my previous communications, I submitted to the Government the necessity of procuring full information regarding the bleaching and dyeing of the tusser yarn, as practised in the various districts of Bengal. I also assisted in the matter to a small extent, but up to this I have never been able to learn what has been done, if anything, towards making public the information obtained on the subject.

Finally, in the papers published on the tusser cocoons (alluded to by you) there are a great many items that could be discussed, and erroneous reports corrected. Will the Government not ask Captain Coussmaker to give his aid towards the said discussions and corrections? I would like to see what he says on the reeling of cocoons at a temperature of 200 degrees.

J. DEVERIA.

FORESTS AND RAINFALL.

(To the Editor of the "Bombay Gazette.")

SIR,—I read in your journal of the 6th instant a very interesting article on "The Effect of Forests on Rainfall." After having given some data obtained on the Continent regarding this very important subject, you conclude by saying that the data obtained are of no use to prove that the forests cause *a greater amount* of rain to fall where it is most essentially needed, *viz.*, in surrounding cultivated lands, and that the searches made on the Continent have led to no *material results*, at least this is how I understand your argument. I perfectly agree with you on the first point, for I was not aware that it was ever intended to show that the benefits of forests extended as far as this. But as regards *material results*, the Continental forest authorities have arrived at very important results, and they are now laid down as absolute laws in the schools of forestry in Germany and France. I shall confine myself to only giving those which relate to the question of "Rainfall and Forests." Given a large tract of forest anywhere, its effect on the country around is—Firstly.—The same as a large tract of water. It moderates all climatic phenomena in the surrounding country, keeping the temperature more or less near to a mean. And in increasing the number of times (not neccessarily the amount) of the rainfalls in a twelve month. This last is nothing more or less than modifying a climatic phenomenon.

Secondly.—It increases the water supply of the neighbouring country.

Thirdly.—It stops the ravages caused by the rush of sudden and great floods of rain.

The consequence accruing from the first is naturally this. If in place of the ocean we had a forest our South-West monsoon would be but slightly altered; but if in the place of the ocean we had only cultivated or bare lands the effect would be certain death to the greater part of the community. This applies also to forests on a small scale. For when a hot wind blows across a forest, its air absorbs a great quantity of moisture from that forest, and by passing over several series of forests or one large forest, it gets more or less charged with moisture, and provided the source of obtaining moisture does not cease sooner or later, it condenses, in the form of rain, on that land over which it may be at the time when it is overcharged with moisture. Of course to lower essentially the temperature of a hot wind and to overcharge its air with moisture, the forest in question must not only be of large dimensions as regards area, or a continued series of tolerable sized forests, but each forest must be complete—that is, it must cover completely the ground on which it stands. Scrub forests and forests of poor growth are next to useless. But given the complete forest as above it acts like a sponge, always retaining moisture in the land and always giving it out little by little to exterior evaporating agents. Then, if we have in India a series of lines of complete forests on all the hills a large tracts of forests in the plains, when a strong hot wind blows, the consequence will be that this hot win dwill get a series of coolings and also will continually take up moisture. Now, if the wind continues to blow it will blow the water-charged air over the land lying between the series of forests. This land or the air immediately about it must get more or less cooled itself; and then will not the rain fall outside the forest? Where does the water come from that falls in the South-West Monsoons? Surely not from the land on which it falls.

On the other hand, if all the hills are bare or have merely scrub or grass, the hot dry wind blows and blows as long as it likes, evaporating at first any moisture that may be near the surface of the land, if the sun has left any, and then this air can never cool enough or obtain enough moisture to cause any rainfall. So dry wind succeeds dry wind, the earth gets parched to an immense extent. Later on when the real rain winds blow, the time the air takes to cool and its water to condense is in direct proportion with the heat that this soil contains or rather the amount of its power to stop condensation; and this heat is less in countries with forests than those without. Hence it is very easy to see the beneficial effects of forests here, *viz.*, of ensuring a rainfall as soon as the rain-charged clouds appear; or, in other words, forests, if present in a sufficient quantity, will ensure a regularity in the period that the monsoon should appear, besides keeping the land surrounding at a more moderate temperature. Who has not seen the clouds that pass over head for weeks before the monsoon commences? These clouds cannot condense because the land has to go through the cooling process, which takes longer and longer according as the amount of forest land is less.

This, then, is one of the effects of forests on the rainfall, and arises from the fact of forests being able to prevent the too rapid evaporation of rain, once fallen, by their regulating powers of respiration.

But forests resist, amongst many others, one great force, *viz.*, *gravity*, which tends to take away water too rapidly when once fallen, and its effects can proceed but slowly in presence of forests. On hills especially where forests exist, directly the rain has fallen it is held by the forest vegetable soil to an amazing extent, and gravity only carries it to lower levels by degrees, and thus we have permanent springs, rivulets, &c. On the other hand, when rain falls on a barren country or a hill side it nearly all runs off at once, carrying with it the soil as it cuts deep furrows and nullahs which increase every year in size. In fact, it devastates the country. This is, of course, impossible where there is a forest.

Of the water that falls in rain a small proportion sinks into the depths of the ground. This is bad enough; but what is worse follows. This rain is not followed, I will say, by any more, in fact, the hot weather commences Then the forces of gravity and evaporation have full play, and in a very short time the whole of the water has disappeared, never to be seen again for another year. I do not say that there are not permanent springs in countries without forests; but by what I have said before it will be clearly seen that the supply to existing springs will be more lasting. Springs and streams which last only a part of the year will become permanent, and many that only last but for a month or so will have their duration perhaps doubled. I cannot enter into a long explanation on the subject of springs, and what in particular places they form and in what places they will not. But of course such places there are and the theories may be known to all your readers. I would therefore, in conclusion, add that forests may cause latent springs to come again into action, but of course where springs never were since the geological formation of the land, forests here cannot be expected to make them. But they act beneficially otherwise in *moderating* and *regulating* climatic phenomena and *stopping* the *ravages of great floods of rain.* So that if the *Commission* now sitting in Bombay cannot arrive at any proofs as to the effects of forests on rainfall or on the direction of the winds (over which last, by-the-bye, they have none), it will always have enough grounds to go on to declare forests invaluable from the points of view that the Continental nations consider them beneficial, and will doubtless see how indirectly they affect famines.

FORESTS.

The Indian Agriculturist.

CALCUTTA, MAY 1, 1879.

HOW PLANTS ARE FED.

THE life of a plant, like that of an animal, is a mystery. No one can tell why it lives, or why it dies. We get no explanation of the real matter by saying that plants are propagated and die, in accordance with certain fixed laws. We are not one whit nearer the secret of existence even when we know many of the conditions under which *growth*, *nutrition*, and *propagation* are possible. In the case of man, "What am I, whence came I, whether am I tending"?—these three questions, which have formed the central magnet, round which the best thoughts of all the ages has gathered, are likely in all time coming, to be as fruitful in thought and speculation as in the old days.

How comes it, that a seed, a germ, cast into the earth, and buried out of sight should find there, those very conditions which are absolutely necessary for its life and growth? A plant may be said to have begun to live, when the heat and moisture of the earth have set up in the starchy substance of the seed, a chemical action by which this starchy matter is changed into sugar, and given up as food to the young *plumule* and rootlets. It is quite

true, that the seed could get heat and moisture without being buried in the ground; but it wants something more, if it is to come to maturity. All that the heat and moisture do for the seed at this stage is to make it possible that it may feed itself till the embryo plant sends out rootlets and little leaflets, down into the soil and up into the air to search for food in every direction, after the store has been exhausted with which every seed is naturally provided. After this has been expended in producing rootlet and *plumule*, after all the albumen stored up in the seed-leaves *(cotyledons)* and under its skin has been used up, the plant is then usually able to feed itself from the various sources from which plant food is obtained. These are the three following, the soil, air, water; plants do not directly feed on solids. Whatever mineral matter enters into the composition of plants and forms part of their tissues, is brought to them dissolved in water. No solid substance can enter a plant as food. All plants are formed of cells, little bags of nearly every shape and varying in size, within the walls of which are certain liquid and granular substances. The walls of these cells are composed of a substance called *cellulose*, they are extremely thin and often transparent, and the cell contents are albumen, a substance having much the same properties as white of egg, woody matter, starch, oil, sugar, gum, and colouring substances.

The cells of an orange are easily seen, as are those of other fruits; but cells are of every shape, round, oval flattened to a disc, few or many sided, produced by pressure, drawn out to a spindle shape, their walls touching, and sometimes broken away, forming short tubes and vessels of different sorts. Some are full of hard woody matter, others have a fine juice as their contents; some are nearly filled by spiral thread-like structures winding round their walls, others again contain colouring substances from which come the varied tints of stem, foliage and flower. These cells and tubes and vessels, whether they can be seen by the naked eye, or only under the microscope have no direct open passage from one to the other. Even the extreme ends of the little fibres of the root, called by the elder vegetable physiologists *spongioles*, have no opening, they are closed cells. Some people are under the impression, that the ends of roots are so many open mouths, leading into open tubes, through which food (sap) enters, and is carried over the plant, as blood is circulated by the veins and arteries over the body. Plants have no sap vessels no tubes with open ends sucking up nourishment. From tip to crown they are altogether cells, big, little, hard, soft, all shapes, serving various purposes in the economy of the plant, but all closed at either end. Whatever then, gets into a plant must be either liquid or gaseous. The question naturally arises, but if the cells are all closed, how can either air or water enter? That they do enter we know, and in the case of water we can see it enter; by placing the growing bulb of a young hyacinth in coloured water, the colouring matter is seen creeping up the long white fibres and ascending the roots. A plant then has the power of taking water in at its roots and sending it over the whole plant, and the only possible way it could gain an entrance is through the cell walls. This it does in accordance with a well known physical law called the law of *osmose* or impulse. Briefly stated, it is as follows:—All liquids of unequal density separated by a porous partition have a tendency to mix, and in this respect it resembles the law of the diffusion of gases. This law can be illustrated in many ways. Here is one: tie a piece of bladder to the end of a fine glass tube, and fill the bladder with treacle and water, placing it in a glass jar of water. In a short time you will see, round the bladder, the water getting discoloured and you may be sure the water is going through the bladder, for the treacle and water are rising in the tube. The same experiment may be performed with sugar and water, or with alcohol and water, or with any two liquids of different densities. This is precisely what takes place in the plant; outside the root there is always moisture, and during the rains, abundance of water. Suppose a cell at the extreme end of the root to be resting in water, a little of its contents will ooze out, as is the case with the treacle through the bladder, and be replaced by a larger quantity of water from without. This cell now contains a mixture of water and its original contents, constituting a liquid much less dense than that contained by the adjoining cells, to which it is attached. The same process is communicated from cell to cell. All plants have not the same *capacity* of imbibing liquids, some take in more, some less. A sun flower has been known to absorb thirty-four cubic inches in an hour. This of course is exceptional; but if we remember that this passage into each other of liquids of different densities is constantly going on in countless numbers of cells, we may readily believe that a plant will have no difficulty in supplying itself with abundance of water if it is to be had in the soil. It may be quite true that there may be no perceptible difference in the density of the sap after it gets up the plant a short distance, nevertheless there is a difference, *endosmoses* and *exosmoses* still go on, till the sap reaches a part of the plant where the swaying of the stalk and branches forces it higher, and the evaporation from the leaves carries off by exhalation part of the cell contents and so carries the sap up further.

IMPROVED PLOUGHS IN THE NORTH-WESTERN PROVINCES.

WE have for some time past heard little, officially or otherwise, of the operations of the Department of Agriculture and Commerce in the N.-W. P. Notices, however, have lately appeared in some of the local papers of the exhibition of implements at Bulandshahr and Aligarh, which have led us to make enquiries as to the progress which the Department has been making in the direction of improved ploughs. We remember publishing several months ago, a paper by Mr. Buck in which was drawn up a list of the "difficulties" which that officer conceived had to be overcome before an English plough could be offered to a native cultivator with any chance of his accepting it for *bona fide* use, the four most important conditions which had to be satisfied being the following:—

1. A reduction of the actual weight to such a point as to enable the cultivator to carry the plough on his shoulder with tolerable ease.
2. A reduction of the draught to within the capabilities of ordinary cultivators' bullocks.
3. A very considerable reduction of the price.
4. A simplicity of manufacture which would render possible repair or even construction by good native smiths or carpenters.

We have now obtained the following particulars with reference to the operations which have been going on under the Department since the publication of the note to which we have referred. In the first place it appears that a very large number of ploughs were brought over by the Department from America and England, and that at the same time Messrs. Ransome and Sims were personally consulted as to the possibility of modifying the native plough, of which a specimen had been sent to them. It appeared evident, however, that the principle on which the native plough is constructed is in itself vicious and that it is absolutely impossible to accept it as the basis of modification. The only course which remained therefore was to take one of the Foreign ploughs as the working model and introduce such modifications as could make it satisfy the required conditions. After trials of various ploughs it was found that the weight and draught were universally prohibitive, but it was at the same time decided that one of Messrs. Ransome and Sims lightest ploughs (the "B. F. O.") gave the best promise of success. A modified form of the plough was made in the bazaar, the price was reduced to Rs. 15, the work done by the plough was extremely good and any fairly good pair of bullocks could drag it with ease. But it was not light enough in actual weight; was not within the dragging powers of the lighter bullocks of the average cultivator, was somewhat complicated in make, and was still not low enough in price. Another model, (one of the American Eagle swing ploughs) was therefore substituted for the last described plough, which, of all the English patterns, had seemed the most likely to succeed, and is still to be greatly recommended where good bullocks are available. Experiments were conducted under the superintendence Mr. Fuller, Mr. Buck's assistant, who succeeded in introducing some effective modifications in the American plough now taken in hand as a model; the make of the plough was simple enough, and it was soon found possible to reduce the actual weight to within the required limits by a few immaterial alterations in pattern; the draught however was

still too great and some farther alterations had to be made in order to lessen the resisting force. Finally, samples of the plough were turned out in the Cawnpore Bazaar at various prices, between Rs. 8 and 10, which settled down to a contract price Rs. 8-8. The construction of the implement is extremely simple and the steel point which is the one part of the plough which is liable to more or less constant renewal is so riveted (on an American plan) as to be replaceable by any ordinary good *mistri*. The weight of the plough as now turned out is 18 seers, the average draught registered by the dynamometer about 1½ cwt., the price is (as above stated) Rs. 8-8 and the repairs or construction of the implement are within the powers of any ordinarily good native workmen. The average depth of the furrow is about 5 inches.

The condition of the problems which the department set itself to work out have therefore been apparently fulfilled so far as they have already been stated. But it has yet to be proved that the plough fulfils all the conditions required by native cultivators and that they will themselves adopt it and bring it into practical use. Even if (as seems likely) the plough can be used without real difficulty by the Indian ryot, yet the *vis inertiæ* which has to be overcome is so powerful that much remains to be done before any extensive introduction of the plough can be hoped for. The first step taken has been to bring it to public notice at the Fairs held in the Bulandshahr and Aligarh districts, in the former of which the fair has some claim to be called an Agricultural Show. Among the zemindars of these districts there is, as it happens, the most intelligent and zealous set of proprietors to be found in these provinces and the result of the exhibition of the plough at the above named fairs has been to interest these gentlemen thoroughly in the matter. But it is more satisfactory to note that a certain number of cultivators, and among them the man in whose field the experiments were tried, have expressed their practical approval of the ploughs by giving orders for them. The next step will be to try them on Court of Wards Estates, and it is expected that by the end of next ploughing season the verdict of the native cultivators may have been obtained.

The plough, as now modified, cannot be brought sufficiently close to the bullocks to enable the driver of the plough to reach his bullocks' tails; but when cattle are fairly trained it is quite possible for the ploughman to drive them himself, and as a matter of fact this is regularly done by one or two intelligent cultivators who have taken the ploughs, while both at Bulandshahr and Aligarh fairs, it was demonstrated even with untrained bullocks, that this was a matter of no great difficulty.

It is understood that the Department are still pursuing the study of the plough and that it is very possible that further modifications or new models may yet be adopted. But they consider that the results already reached sufficiently meet the required conditions to justify them in making a commencement in introducing an improved plough to the notice of native cultivators. Several official and native gentlemen have volunteered a request that ploughs may be sent to them, and there is no doubt that a practical and efficient trial will now be made in various parts of the provinces the results of which will be made known next year.

REAL PHILANTHROPY.

WE have heard of an enterprising advertiser, who "kept a poet on the premises," but to start a philanthropist must have been reserved for Messrs. Warner and Co., Agricultural Engineers of Cripplegate. Messrs Warner and Co., are much interested in the introduction of windmill pumps into India, as a simple means of raising water, and they base their interest in this matter not on sordid considerations of *L. S. D.* but on the more exalted principles of a pure philanthropy. Their spokesman is a gentleman of the name of Goslin, unfortunate in its suggestiveness, and he has lately "thrown off" several literary gems, which reach this country in company with illustrated catalogues of his patron's machinery. One of his productions circulated in this way is in the form of a letter to a correspondent, interested in windmill pumps, and, at the risk of detracting from its excellence as a whole, we cannot help quoting a sentence or two as studies in Syntax as well as in Indian Economy. It must not be imagined that Mr. Goslin writes inconsiderately, or without some sort of experience in Indian matters: "My attention was "directed to these (*i. e.* Indian) famines when quite a boy by an "uncle who lived in my father's house for some years, after having "spent a good portion of his earlier life in Madras, Bombay, and "Calcutta. The monsoons (the hot winds) and the want of "rice have been therefore facts before me as facts recorded, which "made a LASTING IMPRESSION upon my mind some 25 or more "years since." Mr. Goslin's ideas of the monsoons must be as droll as those of the author of "Chatty Letters from India" concerning the perfections of the Indian climate. But although the Famine Question seems to have, to some extent, engaged Mr. Goslin's attention since his earliest infancy, it was not till 1873 that his ideas took definite shape in communication with a Major Rogers, of whom he gratefully, but ungrammatically writes: "Major Rogers, who was a gentleman of great intelligence "and observation and who evidently had not only been in India "as one of the Bengal staff, but one, who, gifted with feeling "for the sufferings of Hindoos, tried his best to save them on "the one hand from the ravages of the wild animals, and on the "other from starvation (but whom (*sic*) as I gather with my "deep sorrow died soon after his return to India in 1875) and "had his mind much exercised as to the introduction of some "small but strong and simple windmills for pumping water "where as he said NOT ONLY were the Hindoos famishing but "also the bullocks which were used for raising the water, but "whose labour was inadequate to produce the desired effect "with them. I tried with him several experiments with "windmills of different models, motions, and constructions." The mind fails to follow this labyrinth of sentences, which indeed is scarcely paralleled by the famous nonsense story of Coleridge beginning "She went into the garden to cut a cabbage leaf to "make an apple-pie."

But, strangely enough, Messrs. Warner and Co. do not rest contented with the efforts of their "poet" and have added a pamphlet of their own, with the modest title "Famines and Droughts a Pressing Question Answered" We recommend this to the perusal of the Famine Commission, if it has not already received their attention Texts from the Bible, religious and moral reflections, statistics and pictures of the best things in pumps are interspersed with a slightly bewildering effect, and the reader is prepared for the suggestion, which is made in the last few pages.—That a society be started to provide the Hindoos with the wells they are too poor to make for themselves, to be worked by windmill pumps—which Messrs Warner and Co. will be happy to supply, *at moderate prices.*

THE SETTLEMENT AND THE BUNNIAH.

THE Bengal Rent Bill has excited more interest, in certain quarters, than the Affghan War. Some regard it as a wise measure calculated to prevent land from passing into the unhallowed grasp of the money-lender, and we were ourselves eager to welcome the provision which aimed at this. Others, of a less hopeful disposition, can see nothing in it, but Mrs. Partington's policy of keeping out the Atlantic by means of the humble domestic broom. And we fear there is force in the argument that, if the social and economical exigencies of the present time, whatever their origin may be, tend to induce the cultivator to raise money on his land, their operation will not be hindered by any regulation which professes merely to place restrictions upon them. Could one indeed discover why the tenant is unable to retain his ancient status, and why the man of money bags, in these days, is so invariably the master of the man of acres,—some tangible result might be expected. Either we should apply ourselves to enforce a remedy, or we should honestly acknowledge the evil to be past our skill. But merely to aim at preventing effects, while the cause is yet undiscovered, is a procedure which has been arraigned, and not unreasonably, as somewhat preposterous. It has been observed with concern that tenants enjoying rights of occupancy are prone to pawn those rights, or even to sell them outright. The

mortgagee or purchaser is of course the money-lender; and the consequence is that the land is passing from the hands of the yeomanry into the clutches of usurers who regard it merely as a profitable investment, and in whose eyes that estate is the best which will endure the most outrageous rack-renting. To meet this evil, a number of experienced men assemble in conclave, and decree that tenant-right shall be alienable only to persons who are really connected with the landed interest. The *boná fide* agriculturist, in short, is to take the place of the city money-lender, as the help of his brother peasant in distress. Unfortunately, there is not the remotest chance of his becoming capable of undertaking any such responsibility; and in the meantime the Bill provides nothing as to the removal of those burdens which make it necessary for the peasant to find help somewhere. The only security which the cultivator can offer is his tenant-right; the only man to whom there is any use in offering it is the money-lender; and until the tenant is relieved of the need to offer security at all, he will continue, by whatever by-paths and indirect crooked ways, to pledge and sell his tenant-right to the banking caste of the towns and large villages. But whence arises the necessity? Ah, that is a question which many are ready enough to answer, but which no Indian Government has ever set itself in earnest to solve. Perhaps we shall not much wrong our rulers if we believe that the reason of their indifference is a secret conviction that any really effectual remedy would imply—if not in Bengal in other parts of India—a considerable diminution of the revenues of the State. Their benevolence knows no bounds in theory; but in practice it keeps to its own limits with obstinate modesty. You shall have long minutes recorded on the desirability of a Department of Agriculture and Commerce, and salaries of equal magnitude attached to the principal officials thereto belonging, but when it comes to a simple act of charity, such as forgiving to an overburdened landowner some part of his debt to the State, high and mighty principles of policy compel the Government to turn a deaf ear to all entreaties, and with averted face and streaming eyes, to pocket its just dues from estates under the auctioneer's hammer.

Private persons, we have said, being blessed with leisure and unfettered by the requirements of statecraft in its most occult branches, and being thus qualified to feel some sort of sympathy with the decaying fortunes of the agricultural interest, have made their own guesses at the reason why landlord and tenant in these days are alike impoverished. It has been surmised that the settlement has something to do with the matter. Of course, this will not explain the alienation of tenant-right in Bengal, where the settlement is like the law of the Medes and Persians, and altereth not. But reasons are not as plentiful as blackberries, and one must take them as one finds them, content if after all one can attain to a partial and local explanation of a phenomenon common to all parts of India. Alienation of tenant-right is not unknown, by any means, in the North-Western Provinces, though it is there unsanctioned either by law or recognised custom, and must, in fact, operate to destroy the alienator's right altogether, if only the landlord thinks it worth while to put the regular legal machinery in motion. Possibly, when the new system of village records has been perfected, we shall be able to collect statistics both of the comparative frequency of such alienations, and also of the relative status of the tenant-right cultivator in various districts. At present one can only make rough estimates in the block, striking out very general results. For instance, we find the tenant-right cultivator most well-to-do in the permanently settled districts of the North-Western Provinces Next to them come the districts of the Upper Doab, where the settlement is notoriously light, having been made in days before imperial exigencies began to lie heavy upon the soul of provincial Governors. Worst of all are the districts where the assessment is known to be heavy, and where, ever since the settlement, the revenue courts have been deluged with applications for leave to enhance rents. Surely we may fairly suppose that the facts are not devoid of a certain significant connection. Where rents are for ever rising, the state of the tenant-right cultivator is the least to be distinguished from that of the tenant-at-will. But the enhancement of rents is a phenomenon as demonstrably connected with the settlement as the tides are with the movements of the moon. It is worth while to say a few words upon a matter of such grave import, though it has hitherto remained in the obscurity which delights to cover all important questions bound up with the every-day life of the population of India. A wave of settlement passes over the land, sweeping into the treasury sums unknown before. From one point of view, the result is satisfactory, and the attention of the Government, perhaps not unnaturally, has hitherto been engrossed by this aspect of the matter. And yet we should do wisely, in this as in many other questions of Indian administration, to recall the words of the Scottish monarch—though far be it from us to suggest any invidious comparison between his style of management and our present paternal system—

> If it were done when 'tis done, then 'twere well
> It were done quickly: if the settlement
> Could trammel up its consequences—

and was not followed by a second wave of rent suits, we should be spared some painful doubts about the operation of our main revenue machinery. Estates are assessed upon their potential productive powers; and landlords soon find it necessary or expedient to raise rents to the level of the settlement officer's estimates. Hence follows the abolition of all those little privileges which help to lighten the prevailing penury of the agricultural condition. The village headman ceases to enjoy his few acres at a nominal rent; the village carpenter, blacksmith, and other craftsmen, are obliged to surrender their patches of land to tenants who will pay for them at a larger figure, the ex-landowner finds himself deprived of the consideration hitherto vouchsafed him, and is placed on a level with neighbours who have not his title to the plea of decayed gentility; while the common tenant-right cultivator is called on to fight for his life against a sudden increase of his burdens by fifty or a hundred per cent. It is true that none of these changes can be made without the order of an English officer who has rendered himself personally acquainted with every man's case But not the most laborious and judicious officer can wholly save the cultivator from the legal worsening of his lot. If all enhancement suits were summarily thrown out, injustice would be done to the landlords with whom the State has just concluded a bargain on the assumption that they can get more than they have hitherto done out of their tenants. The blow may be eased off a little by due allowance for the tenant's present circumstances and future expectations, but in the end it is sure to fall. Adjudications of this sort are painful enough to a sensitive officer. His duty takes him into the fields and villages to wander all the morning over poorly cultivated fields, yielding indifferent crops, and owned by an undergrown and underfed peasantry, for the most part in debt, and all half clothed and wholly illiterate. On one side is the landlord, reciting fabulous stories of the productiveness of the soil; on the other are the tenants in a body, crying that the earth refuses to yield her increase. Neither party sees the slightest difference between the truth and a lie, nor feels any touch of shame when detected in the latter. Amidst this Babel of protestations, objurgations, and invocations of all the gods, the hapless Englishman moves from field to field while the sun is getting higher, trying to make his notes and to arrive at a fair average rent-rate for every class and condition of soil. Happy is he, if, after an examination as thorough as he can make it, he feels himself fairly able to refuse the enhancement demanded. But it more frequently happens that he must record a decree which, while amply warranted by law and by the facts of the case, still leaves him sadly aware that he has added another straw to the burden of that patient and overloaded animal, the Indian agriculturist. Nay, it will be said, is the tiller of the soil to be exempted from paying to the State his fair share of that increased value which has been conferred upon the soil by the State itself? An answer that would square with economic principles might no doubt be found. But a more practical answer is afforded by the actual condition of the peasantry in Rohilkhund of the North-West,—the most favoured tract of the most intellectually governed province of British India.

INDIAN HORSES.

HERODOTUS somewhere praises the ponies of Tirhoot. "The horses of that country," says the father of history, "are small, but of marvellous endurance." If the old Greek were alive now, he might tell the world his views upon polo, a game to which the Tirhoot ponies of his day do not appear to have been accustomed, for we find no mention of it in his communicative volumes. The quality of endurance, however, is one common to the Indian ponies of his day and of ours, whether natives of Tirhoot, or of the Deccan, or of up-country districts. It is in truth a quality which is often put to the test. Native ponies are constantly called upon to traverse long distances without a halt. The feat performed by Daya Ram's pony is historical That obstinate lord of Hatras, in the first quarter of the present century, put the Indian Government to the trouble of shelling his fort a whole summer day, by way of a coercive process for the realisation of the revenue which he refused to disgorge. In the night he fled, and before another night had fallen, his pony had carried him to the fastness of a brother chieftain in Bundelkhund. History does not say what became of the brave little animal,—whether the long march killed it, or whether it lived, as it deserved, to an honoured old age. Judging from the treatment of modern ponies by their masters, we fear there is small reason to hope that Daya Ram cherished much gratitude. Perhaps the fault is one characteristic of horse-owners all over the world. Even the romantic Fitz James, in Scott's delightful *Lady of the Lake*, has only a few common-places of regret for the good steed which he has ridden to death, and we all know how an humbler poet, who could, however, plead practical experience in the matter—Bloomfield, the farmer's boy—has depicted the farmer sending old Bayard to the dogs. Still, if an English master has little pity for his horse when past service, he does not, like the native of India, keep it at the point of starvation during its working days. The Indian Government, they say, is buying up ponies for the Cabul commissariat. These will have at least one advantage over the Indian camel, now become almost a thing of the past. They are much better accustomed to starvation. The camel, being a valuable beast, does get regular meals when at home, and one may presume, from recent mortuary returns, that it feels the want of them if driven fasting more than a week or ten days. The pony, on the other hand, costs about one-tenth of the price, and is supposed to feed himself, which he generally manages to do after a fashion. He is, in fact, an old campaigner from his birth, and therefore better adapted to keep body and soul together, without grass or grooming, in a land which produces for the most part nothing but stones and men. He is already accustomed to march thirty miles on an empty stomach, with a fat old landlord, or perhaps landlady, on his back, and expects nothing at the end of it except leave to do a little grazing on his own account, or may be a handful of thin grass is shaken down under his nose. Poor little fellow, he has need of all his historical virtue of endurance; and nobody can suppose that it will not be tested to the uttermost, if the day comes, among the rocks and deserts of Affghanistan.

The other quality, that of smallness of stature, is less desirable, but equally permanent. It is a trite saying that Indian horses are all undersized. So, too, for the matter of that, are the men and women; and the cause is no doubt the same in both cases, to wit, insufficient nourishment, and climatic conditions unfavourable to the development of robust vigour. The legs of the ordinary native are a lamentable spectacle; and those of his pony are worse. This results, in the case of the latter, usually from overloading while the animal is young. It often shews itself in very pitiable shapes. The curious naturalist might discover in India an equine species which is plantigrade, walking on the whole foot, like the bear, instead of on the toes only, as a horse should do. Yet even the common pony of the country, when he gets fair play, vindicates the national reputation in size and strength as completely as the tallest Sikh or the sleekest Poorbea sepoy. There is no dearth of polo ponies, though players complain of difficulty in getting them,—a difficulty due not so much to any real deficiency of supply, as to the want of a medium between the village-owner and the man in cantonments who desires to buy. A good pony is notoriously cheaper in India than in England, and if a little smaller, is probably for that reason all the better suited to the game. But after all, it is not by its ponies that the merits of a horse-breeding country must be judged; and when one turns to the horse proper, there is no denying that India falls far short of the home standard. One has only to take up an English and an Indian newspaper, and turn to the advertisements of horses for sale. The average height in the former will be found to be between fifteen and sixteen hands; in the latter between fourteen and fifteen. And this inferiority in height is accompanied by similar inferiority in bone and sinew. The Indian horse is light, like the man he is meant to carry. Our irregular cavalry regiments ride, on an average, from nine to ten stone per man; an Hussar, with his accoutrements, will weigh fourteen or fifteen. The difference is as old as the days of the Crusades, and as extensive as the geographical distinction between the warm countries of Asia and the temperate climes of Europe On the great Asiatic table-land, another breed of horses is met with, rivalling those of Europe in bulk and thews and large appearance. It would be worth while to try the result of a cross between the Turkoman horse and the English thoroughbred. The vast steppes of Turkestan seem intended by nature for a breeding-ground. Nothing corresponding to them is to be found in India; and their pure bracing air imparts a kind of life very different from that breathed by the hot-house atmosphere of this country. Yet India also has her breed of horses, more than one or two. Kattyawar has long been famous for its little horses of high spirit and uncertain temper, marked with that odd cervical stripe which seems to argue some distant strain of blood from the wild ass which still haunts the Runn of Cutch, lately left unvisited by Sir Richard Temple. The Deccan has its wiry race of fourteen-handers, descended from ancestors that carried many a bold Mahratta cateran safely from before the English guns. In the Upper Doab survives a breed of horses which boasts an Imperial origin. Aurungzebe, returning from conquests in Southern India, brought back with him, as a precious prize, two generous mares for the royal stud. Encamping on the northern bank of the Jumna, in that difficult country of ravines and scrub, the Emperor's wealthy train offered a splendid chance for booty to the wild Jats who have had their abode there for ages. They came by night and cut out the two mares, and carried them away northwards, where their offspring are to be found to this day, each with its family tree to prove a descent otherwise abundantly evidenced by unmistakable signs of blood, although the universal defect of lightness is not all redeemed by beauty and speed. In Rohilkhund, along the Ram Gunga, where broad river meadows, rich in clover and grass, present the best pasture ground the peninsula has to show, a stronger race of horses was bred in more favourable times, and still continues, though less and less, to furnish remounts to our cavalry and horse police. Cultivation is encroaching upon pasture; and the old land-owners, who prided themselves on their mares, are gradually sinking under debt and improvidence, while their successors, mere usurers and scribes, value nothing higher than an ambling pad. The sportsman who seeks duck and wild geese by the margin of the Ram Gunga's many pools, will still often notice a promising young foal trotting away scared at his approach, or grazing by the side of its mother, whose lean intelligent head tells of good birth and better days. And here and there he will find an English or an Arab stallion lent by the Government to the land-owners, who have had their mares approved and branded as fit for breeding purposes.

It is a pity that some little trouble is not taken to improve these various breeds of horses by the wholesome stimulus of competition. Here, as in most Indian matters, much rests with the powers that be. Horse-breeding in this country will never go on satisfactorily by itself. There is a market, but it is too distant to exercise the required effect upon the horse-breeder. We mean distant in point of time, rather than place. A foal needs four years' keeping before it becomes a marketable commodity; and it is vain to expect a native landlord to look so far forward. He will not devote care and attention to an object removed from him by the space of four whole years. And

so it happens that the foal is neglected, and the young horse is left to grow up as it likes, and to pick up a living where it can. Before the period is out, the owner grows tired of keeping an animal for nothing, and takes it into work before it is fit to carry a load. The consequence is either immediate breakdown, or a strain which shews itself in after years; and thus many a fine young horse is spoiled for life. Now, the Government might very judiciously interfere to prevent this, by substituting a more interesting object than the prospect of sale after so long a term. The owner's pride in his young horse might wisely be stimulated by offering him an opportunity of winning commendation and a prize for it several times during the interval. This could be managed by means of annual horse-shows in central places near the principal breeding districts. Probably the outturn of horses would be poor enough to begin with; but in a year or two the system would have become familiar to every one concerned, and horse-breeders would bring their young stock readily for inspection and judgment, while the prizes, besides being valuable with a view to future sale, would more than cover the cost of transit. Exhibitions of this kind already exist in a fitful sort of way. Certain principles of judging have been approved by the Government, and there is even a supply of printed certificates, so that no details are wanting. But all is marred by the long and capricious intervals at which the shows are held. Horse-breeders cease to take any interest in them when they come once in half-a-dozen years. They should be annual institutions, like any other large fair. Every horse-breeder in the country should be encouraged to bring his whole stock once a year to be examined, and to get prizes, if judged up to the mark. Such meetings would be frequented by purchasers, and the horse-breeder would have the double advantage of a good market and of the instructive lessons to be derived from a wide field of comparison. Competition at these annual contests would soon become an important factor in the improvement of the breed of horses. Every exhibitor would try to bring his animals to the test in the best possible condition. We should soon cease to see those ragged coats, prominent ribs, prematurely tasked legs and back, with an occasional galled shoulder or withers by no means unwrung, which deface so large a proportion of the young stock at the present horse-shows. The subject is one well deserving of attention. The stud system has rightly been abolished. No Government can breed horses for itself, any more than it can undertake to give rations to all its servants. But there is a medium between this and total neglect of the conditions under which the offspring of Government stallions, supplied gratis to land-owners, is allowed to grow up during the decisive years of its life.

MYROBALANS.

THE fruit of the Beleric Myrobalan (*Terminalia belerica*; N. O. *Combretaceæ* vern. (Bahera; fruit Har, Harra). Extensively grown in the Punjab; Eastern part of the Sewalik tract; Kangra district; hills and north of the Peshawar Valley; and generally in the northern and eastern parts of the plains of the Punjab, where the climate is tolerably moist for the greater portion of the year, as in the dry arid parts to the south and west it does not thrive.

It flowers in the spring and the fruit—which consists of a nut, enclosed in a thin exterior rind—ripens in the ensuing autumn. The tree attains a considerable size, 70 to 100 feet high, the trunk being regularly shaped, tall and straight, up to 10 feet in girth (occasionally 15 to 20 feet). the branches spreading considerably, forming a broad massive crown which gives the tree a very handsome appearance.

The trees are valuable, the produce of a single one has been known to sell for Rs. 2,000; the seeds are obtainable, generally, at from nine to twelve seers per rupee, though one seed has been known to fetch one rupee!

Economic Uses.—The *leaves*, in Kangra, are considered the best fodder for milch cows; and they are also used in dyeing. The *fruit* is employed as a mordaunt in dyeing cloth and leather; in tanning; making ink; used as an aperient medicine, a tonic, an astringent, and in mucous discharges from the lungs and bowels: when only half ripe, it is used as a purgative; it is also eaten by cattle, deer, goats, monkeys, and sheep. The *kernels* are eaten, but are considered intoxicating; they yield an oil. The *bark* yields an insipid gum The *wood* is yellow or light-grey, coarse open grain easily worked, but not durable chiefly owing to its liability to the attacks of white ants and other insects; in Kangra it is considered unlucky to use it for building purposes: previously to being used for building, it is advisable to season it by steeping it for some time in water: it is also used for packing cases, small boats, planks: a cubic foot of green wood weighs about 60 lbs, one-third of which it loses in seasoning.

A second variety is *T. chebula* (vern. Har, harar), which is occasionally cultivated in the Sewalik tract up as far as the Peshawur valley. The *wood* is durable, hard, heavy, yellowish tinge, wavy outline, making up into pretty furniture, it takes a good polish. The *fruit* is used by dyers as a mordaunt; also in tanning and in medicine as an astringent. The *bark* is also used for tanning and dyeing. The *galls* make writing ink.

A third variety is *T. arjuna* (vern. arjan) occasionally cultivated in the Punjab as far west as the river Ravi. It is a fine handsome tree, with greenish bark—seldom entirely leafless—attaining an altitude of 70 to 100 feet, the trunk having large buttresses for the first dozen feet from the ground. There are some very fine trees near Kangra. The *wood* splits in seasoning, is subject to the attacks of white ants, and is only used for agricultural implements and carts. The *bark*, in Kangra, is used to heal sores.

A fourth variety is *T. tomentosa* vel *Pentaptera tomentosa*. Grows in the Sewalik tract, as far as the river Ravi, and in places is found as high as 4,000 feet. The *wood* is used for building—though its durability is uncertain and it splits in seasoning—it makes good charcoal and potash and in burning as fuel it throws out great heat; the branches make good cattle fodder. This tree coppices well. The *bark* is useful for tanning.

The foregoing trees thrive more or less all over India, though this short description merely refers to the Punjab.

G. P. P.

EDITORIAL NOTES.

MR. A. DECLOSETS, C.E., has appealed to Government in behalf of science as well as of public utility for the loan of the *boring apparatus* in the Public Works Department Stores. Mr. DeClosets says—"There is a gentleman who is willing to go to the expense of boring an Artesian well in the tertiary and cretaceous formations about eight miles west of Pondicherry and upon the English ground under my direction. But he has not a proper apparatus to reach the depth required, and as such work requires much care and good implements, I have been induced to make you my demand. Should you agree to grant it, I will be bound to return the boring apparatus to Government after having used it, and in good condition. On a similar occasion when I was boring in the Madras Island (for a projected harbour) I had the loan from the Public Works Department Stores of a boring apparatus which I returned safely after." Mr. DeClosets refers to what has recently been done at Pondicherry in sinking Artesian wells, and thinks these wells will be valuable for irrigation purpose; there are now many inquiries about the practicability of these wells in several localities, and several borings have commenced. His opinion is that the water obtained at Pondicherry proceeds from the Poncar and perhaps Gingee rivers, penetrating the sands 10 or 12 miles westward inland. The boring apparatus asked for by Mr. DeClosets will be supplied to him on loan. The Government regard the subject as one of great interest, and will be glad to learn the results of Mr. DeClosets' attempts to obtain water from Artesian wells.

THE decline in the mulberry cultivation of Mysore is a result we presume of the famine. In the last administration report for the province, allusion is made by the Chief Commissioner to this decline. Mulberry is cultivated of course with a view to the feeding and rearing of silk worms, from which the raw material is obtained for silk manufacture, and formed the principal means of subsistence and income of many hundreds of families, specially of the poorer classes of Mahomedans. The cusbah town of Oscottah was at one time surrounded by numerous gardens of the mulberry tree: the old foot ditch of Kolar together with a good deal of land below the Kolar tank was cultivated with the same; while thousands upon thousands of mulberry trees were cultivated near Cosepett, Biddad, Chennapatam, Kingerry, and other places, which all belonged to or were tended by Mahomedan silk weavers. Within the past few years, however, the silk industry, which at one time formed no small

portion of local produce, has so far declined as to attract the attention of the local Government. Many years back, it will be in the recollection of some, that a silk factory, on a large scale, was projected at Kingerry, where *pucka* buildings, machinery, &c., were all erected; but the speculation never paid, and after sinking a large sum of money the Kingerry factory was finally abandoned and brought to the hammer. The silk worms do not appear to thrive so well as they did formerly, whether it be the fault of feeding—for perhaps there may be some disease in the mulberry trees—or any other reason, we cannot say, but it is a matter to which, should the Government, as it promises, give consideration it will result in to benefit the province and a large class of poor people.

THE average prices of middling Orleans and fair Dhollera cotton during the past 25 years, and the present prices, are given as follows:—

	1. Per lb. d.	2. Per lb. d.		1. Per lb. d.	2. Per lb. d.
1854 ...	5·37 ...	3·62	1867 ...	10·84 ...	8·53
1855 ...	5·76 ...	4·05	1868 ...	10·75 ...	8·50
1856 ...	6·36 ...	4·80	1869 ...	12·37 ...	9·81
1857 ...	7·82 ...	5·39	1870 ...	10·18 ...	8·12
1858 ...	7·00 ...	5·50	1871 ...	8·79 ...	6·58

1866 ..	15·78 ...	11·95	Present price	5·62 ...	4·06

The period of very lowest depression in the Indian Export Trade was from about 1846 to 1854 when the Crimean War became the occasion of opening the trade in oil-seeds with India. The figures in the above table are very discouraging. Prices have gone down steadily for the last 15 years and are now lower, than they were 25 years ago. The staple was just five times its present price fifteen years back, while there seems to be no limit to the fall that yet impends.

GREAT efforts are being made to improve the agriculture of Guatemala, yet the wheat crop of 1878 failed, and the Government was forced to reduce the duty on imported grain one-half. Coffee cultivation is being largely extended, and liberal terms are offered to immigrants to settle in the country and introduce permanent improvements in the way of irrigation works, roads, &c. Attempts are being made to open the oil deposits on the Atlantic coast in the neighbourhood of the Lampara and Vincent rivers. The trade of the Republic is steadily increasing. The exports during the past year reached nearly 4,000,000 dollars, as against 3,773,185 dollars in 1877, or half a million more than in 1875. The principal article of export is coffee, which represents the great bulk of the figures above quoted, but cochineal, wool, and sugar are considered items of trade. England supplies more than half of the articles imported into the country, France, Germany, and the United States the bulk of the remainder.

THE plantain has never become a favorite fruit in England but seems to be prized in the States. The annual amount of *bananas* imported into Boston during the season is about eight cargoes, worth 6,000 dollars to 7,000 dollars each, making, with 50 cargoes received at New York, a total of about 375,000 dollars as the value of receipts at New York and Boston. The banana season begins in March or April and extends into August. The North Coast of Cuba seems to furnish the fruit chiefly, shipments are also made from Aspinwall on the Spanish Main, from Trinidad and Jamaica.

ALTHOUGH Indian Model Farms have not been very successful, they have been the means of diffusing valuable knowledge amongst the cultivators. In the beginning of last year the Secretary of State requested to be furnished with information regarding the general working of the Farms throughout India. A *précis* of the reports has been prepared by Mr. Hume, and Madras of course is far ahead of the other Presidencies owing to the energy and experience of Mr. Robertson, who is revolutionising the agricultural world of the benighted Presidency.

In the Madras Presidency good and useful work is being done under the supervision and guidance of Mr. Robertson, the Superintendent of Government Farms. Attached to the Sydapet Farm, on which experiments of various kinds are tried, is an Agricultural College in which a complete course of agricultural instruction is afforded, and which is intended eventually to accommodate upwards of one hundred students. In view to a further diffusion of information, Mr. Robertson has proposed the establishment of small agricultural experimental stations all over the Presidency, each being placed in charge of a trained agriculturist, who is also to conduct an elementary agricultural class. This scheme is, however, at present in abeyance for want of funds.

Mr. Roberston's services are at last eagerly sought by all who would make the model farms successful. The versatile Governor of Bombay has decided that the Western Presidency is to have an Agricultural College, and is doubtless prepared to deliver a long lecture to the students on practical agriculture, as he gave the medical students the benefit of his views on the theory and practice of medicine the other day, and has instructed the volunteers in the science of musketry. To make the Farms attractive it is desirable to have Agricultural Schools attached to them, and the various Local Governments are at last requested to bring about some such arrangement. The Department of Agriculture and Commerce in the North-West under Mr. Buck has been attended with such excellent results, that Government contemplate similar departments in other parts of India. Lord Lytton asks for an early opinion from the Bengal Government, and the Local Governments and Administrations.

THE almost general practice in India of sowing mixed crops was recently made the subject of some remarks in a letter to the *Englishman* signed "D.N.R." The writer says:—

"Thou shalt not sow thy field with mingled seed" is one of the laws laid down in the Bible, and an uncommonly good one it is too. I quite believe that the pernicious custom of sowing mixed seeds has as much as anything else to say to the poor state of the crops and the lands. Moreover, I am prepared to swear that more *rubbee* was ruined during the present season, by this system of agriculture than by drought and frost put together. I particularly noticed how promising crops of wheat and barley lodged and spoiled after the mustard plant was gathered.

We commend these remarks to the attention of Mr. Hume's department, and particularly to the very able Director of agricultural matters we have in the North-West, in Mr. C. E. Buck. We suspect, however, that the matter is far from being so simple as "D.N.R." imagines, and that the ryot is able to give sound reasons for a practice that is almost universal in India. In prosecuting some enquiries in the Agra district a year ago, as to the condition of the people, we found that they were living upon *chuppaties* made of what is called *bejhur* in the quotations of the local paper, and *bejhara* in Carnegy's *Technicalities*, a mixed crop, generally of gram and barley. Strange to say, none of the gentlemen we spoke to on the subject, knew what this *bejhur* meant. They insisted that it must be *bajra*, a millet of the kharif crop, while *bejhara* is *rubbee* produce. It was not until we made our own house servants bring *chuppaties* before us in the actual form in which the poor consume them, that we ascertained definitely what this *bejhara* was. It is a common enough statement that the people prefer *chuppaties* of *bajra* and *jowar*, to the superior grains, and it was made to us at Lucknow only a few days ago, by gentlemen who ought to have known better. It is the deep poverty of the peasant, and nothing else, that compels him to live upon the coarsest and least nutritious grains, and to see the whole of his wheat crop taken to pay the demands of the State, the landlord, and the mahajun.

MR. BUCK is, we believe, going home to recruit his health, but we have little doubt that this subject of 'mixed crops' will command his notice, now that D.N.R. has made so important a statement concerning it. The uncertainty of the rainfall will, we suspect, be found to be one main reason for the practice, the cultivator sowing two crops, that, if the one fail, he may at least obtain something from the other, the crops not being equally dependent on the rains. D.N.R. can know very little, however,

of the real condition of the people, when he proceeds to make such proposals as the following :—

"The ryots should be made to take out licenses for the cultivation of such crops as opium, sugarcane, tobacco, indigo, and all oleaginous seed plants. An establishment of peons should be kept to see that these crops are not cultivated without a license, and these peons should be punished by flogging and fine when convicted of oppressing the ryots, or for bringing false charges against them. Good, active officers over these men could keep them in perfect check, as God's earth and the crops thereon will furnish all the witnesses required in a case brought by either peon or ryot. It would not take long to check all the taxable fields in a village; mixed crops of oil-seeds and food-grains should be charged for as if they only bore taxable produce. This in itself would check the evil of sowing mingled seed."

He then proceeds to show that the opium soil of north Behar is in process of exhaustion, and says :—

"If the average produce per beegah of opium in north Behar for periods of six years from season 1848-49 to 1871-72 inclusive was as follows :—

		mds.	s.	ch.	
From 1848-49 to 1853-54	...	0	6	4½	per beegah.
" 1854-55 to 1859-60	...	0	4	9¼	"
" 1860-61 to 1865-66	...	0	5	2⅛	"
" 1866-67 to 1871-72	...	0	4	8	"

"The above shows a decrease of nearly fifty per cent. in the produce gathered per beegah during a period of thirty years, and the result of the last six years will show a still more alarming decrease, as I am certain the average produce of north Behar has not been three seers per beegah from the land cultivated in opium. If the present system is continued, what will the produce be fifty years hence; and yet the cultivation of this crop on a large scale in India is still in its infancy, having been introduced by the English."

We are under the impression that the last statement is an error, but do not stay to verify it. If D.N.R. is right, however, as to this rapid deterioration of the soil, the opium agencies at Benares and Goruckpore should be required to report upon the matter, at length and at once. As the manufacturing season has just opened, Dr. Shepherd's hands will probably be full until August or September next, but he probably is the right man to make the enquiry. D. N. R. would have the opium monopoly abandoned and poppy land assessed instead at Rs. 10 the acre. How this would improve matters is not by any means clear, but D.N.R. will perhaps return to the subject. As it is, he simply says :—"The opium monopoly should be thrown up, "and a heavy tax of, say, Rs. 10 per acre might be imposed "instead for those who choose to cultivate this crop."

But this is not all. The unhappy cultivator's ways are to be corrected by "a light tax laid on all his crops, except food-grains, roots and tubers, to check the evil of sowing mixed seed. Great permanent benefit will thus be done to the agriculture of the country, and the Government will realise several millions sterling of revenue without any oppression or bother whatever."

But the cultivators as a class, are already groaning, literally 'groaning,' under the existing taxes, not because of their weight in themselves, but because of their abject poverty and total want of resources to meet them. A two-anna tax per acre is light enough, it will be admitted, but what is the man to do who has not got the two annas to pay ? Now this is the state of the peasant-cultivator under our rule so widely, that we are beginning to regard his condition with despair. The License-tax, light as it may seem to men sitting in the Council room at Government-House, *is afflicting the people so heavily, that we are reflecting upon ourselves constantly for having given it our support.*

Our readers know *why* we supported it, and how the Government that imposed it, has broken faith with us and with the people, and misappropriated its proceeds, "a misdeed of the first order," as one of England's greatest statesman, writes to us. But D.N.R. is both sanguine and heroic, where we are depressed under the presentiment of coming evil. He says :—

"If throughout British India non-food crops were taxed at something like the following rates, the agriculture of the country would flourish, and the Government would derive from 8 to 10 millions sterling of revenue :—

Poppy	...	Rs. 10	per acre.
Tobacco	...	" 5	"
Sugarcane	...	" 3	"
Indigo	...	" 3	"
Cotton	...	" 2	"
Castor seed	...	" 2	"
Mustard	...	" 2	"
Linseed and other oleaginous seed plants mentioned above,		As. 0	"

"You may say that the ryots would rebel and cease to grow these crops. So much the better for themselves and the future prospects of the country if they do, say I; as better men than they would take up the cultivation, and willingly pay the taxes mentioned above."

All we can say is, let the Government find out who "D.N.R." is, and try him with these new taxes by all means. As to imposing them upon the cultivator, the proposal is simple insanity.

We hear that Messrs. Begg, Sutherland and Co.'s experiments at the Poosah farm with the cultivation, and more especially the curing, of tobacco have been very successful. The public would be glad to know something of these experiments we are sure, and the Bengal Office may possibly be able to tell us what has been accomplished. The Poosah Farm was presented to the local Government about five years ago by the Government of India, for the special purpose of improving the agriculture of the province, but we have heard nothing of it since. Indian tobacco hitherto has simply been sun-dried or hut-dried, and if Messrs. Begg, Sutherland and Co. succeed in 'curing' the leaf, so as to make the tobacco valuable in the European market, we shall very quickly see Indian tobacco forming a new export of great importance in our Customs returns.

Mr. Robertson, the chief of the Madras Agricultural College has been putting his students through a course of gymnastics and has reported the results to Government. He formed a class of twenty-eight members who were exercised with dumb-bells, vaulting, and parallel bars, &c. The students who went in for gymnastics, Mr. Robertson tells us, "have enjoyed remarkably good health and are much better fitted for their training for out-of-door employment than they were previously." So satisfied *is the Principal of the efficacy of a good* combination of gymnastics and agriculture, that in a subsequent communication to the Board of Revenue he proposes to hold an athletic exhibition. He says, "I have the honor to request that the Board will be good enough to permit me to offer prizes to the aggregate value of Rs. 50, to be competed for by the students of the gymnasium class and other students of the School of Agriculture at a public competition in gymnastics, &c., I propose to hold some time about Easter, or earlier if arrangements can be made." Such an outrage on official sobriety as Mr. Robertson proposes to commit is too much for the Local Board of Revenue, who reply: "The Board are of opinion that the teaching of gymnastics is not calculated to further the cause of agricultural science. The case of youths whose studies are sedentary forms no parallel to that of generally older men whose training is largely conducted in the field." The proposed public gymnastic competition seems calculated to raise public doubts of the seriousness of the agricultural education imparted at the institution. The Board suggest that the gymnasium be discontinued. We are glad to find however, that the Duke of Buckingham declines to be bound over by the red-tapeism of such a respectable body. The Government Minute on the subject says :—"The Government do not agree with the Board in thinking that the gymnasium should be discontinued. The public demonstration, however, which has been proposed, is inexpedient." So Mr. Robertson will be allowed to retain his gymnasium which is "not calculated to further the cause of science."

The high estimation in which sewage irrigation is held by the cultivators is proved by the fact that the ground of the sewage farm at Allahabad brings in Rs. 20 and Rs. 40 per acre. The latter price includes irrigation. As market-garden ground, the farm holdings are eagerly sought after, and a

considerable addition to the income of the Municipality is the result. In Bombay, the utilisation of the town sweepings in the reclamation of the Byculla flats, although objectionable in many ways, has proved a valuable source of income to the Municipality, as the ground always commands a high rental, and applicants for fresh reclaimed land are never wanting. At Cawnpore, where some experiments in sewage farming have been tried lately, land has been let at more than Rs. 20 per acre.

The principal operations on the Cawnpore model farm during the past years were a follows :—Trials of English and improved ploughs, a trial of new seed wheat, experiments in subsoil drainage, trials with waterlifts, and winnowing by machinery. The drought which prevailed last year interfered considerably with the general work of the farm, and with most of the operations detailed above. The native cultivators do not appear to appreciate the English system of ploughing, although no pains have been spared to demonstrate the vast superiority of the process to their own primitive system. One of their principal objections appears to be that they are unable, when driving an English plough, to reach the bullocks' tails, and no well-conducted animal of that species, it is asserted, will work thoroughly without having his caudal appendage occasionally twisted. Another objection is that the ploughs are too heavy for the cattle. Some samples of the American plough which were sent out by the Secretary of State are the most suitable, and are more likely to be adopted by cultivators than any other kind. We have referred to the subject of the introduction of Improved Ploughs at length elsewhere. The trials with new seed wheat proved that the native seed was quite equal to that experimented with. The results of the trial of winnowing by machinery were very favorable, and it is probable that these machines may meet with the general approbation of the cultivators.

It is proposed to start a company at Agra, to be called the Charua Agricultural Company, Limited, for the cultivation of some land in the Hoshungabad district. The prospectus tells us that—

The land borders on a perennial stream, and is intersected by nullahs. Water is found generally at a depth of 5 or 6 feet below the surface. It is very fertile, and contains an inexhaustible supply of wood for agricultural purposes and fine grass for cattle. It will require very little clearing, so that within one year from the commencement of the operation, it is confidently expected that the first harvest will be gathered. Again, the land is almost centrically situated as regards the Presidencies of Bengal, Bombay, and Madras, and is only five miles distant from the Hursood or Kukian station of the Great Indian Peninsula Railway, so that the produce can be most cheaply and conveniently sent to the best markets of the world. The rent of the land is moderate and reasonable.

It is proposed to issue 3,000 shares at Rs. 10 each. An experienced manager is to be appointed, and a meeting of shareholders called as soon as 100 shares have been taken up. The project, which is entirely a native one, deserves the support of all who desire to encourage agricultural advancement amongst the natives of India.

A Correspondent writes :—There grows in South America a wonderful tree which has been called the cow tree, from the fact that it yields a milk so like that produced by the cow, that the inhabitants use it for domestic purposes in lieu of cow's milk. A French chemist has lately carefully analysed several specimens, and finds that in its properties, this curious vegetable production much nearer approaches cream than milk. In fact it is much more abundantly rich in butter and saporific matters than milk. Such a tree would be invaluable in India, more especially in such places as Wynaad, where milk is often with difficulty procured. The tree grows in Venezuela and New Valencia, and its botanical name is *Brosunum galacto dendron*; the natives call it palo de vacha. It grows in extensive forests, and attains a height of 100 feet or more.

The Department of Agriculture and Commerce in the North West Provinces and Oudh has introduced a system for the collection of trade statistics, which is likely to lead to valuable results. At present the returns do not exhibit that degree of accuracy which is desirable, but as soon as the system is thoroughly established, these inaccuracies may be expected to disappear. Mr. Buck is a most indefatigable worker, and in his hands the scheme is pretty certain to prove a success. In connection with this matter, we may also notice the endeavours which the same Department has been making for the promotion of trades and manufactures. The manufacture of Rhea fibre has engaged attention, and also the manufacture of glass and pottery, and the development of the silk and tobacco industries. These are some of the more important matters which have occupied the head of the Department for the past year.

COMMUNICATED AND SELECTED.

LADY BIRDS.

These little insects feed on the plant-lice (*aphides*)—parasites which prey on and injure plants and trees.

They appear in England, sometimes in immense swarms, and spreading over the fields, have caused needless alarm to the farmer to whom, far from being a pest, they are a blessing, from the fierce war they wage against his enemies the *aphides*.

In 1807 the shores at Brighton and nearly all the watering, places on the south coast were literally covered with them, to the great surprise and alarm of the inhabitants, who were ignorant that their little visitors were emigrants from the neighbouring hop grounds, where, in their larva state, each had slain his thousands and tens of thousands of the *aphis*, which, under the name of the "fly" so frequently blasts the hopes of the hop-grower.

The peasants in France collect and place them on trees and shrubs infested with *aphides* and style them "bêtes-à-Dieu," honouring their useful qualities; whilst the English name of 'Lady-bird" does homage to their beauty.

Some of the species are widely distributed, such as the very common *coccinella septem-punctata*, which extends its range over all Europe, and parts of Asia and Africa. They are frequently found on the summits of mountains at a very great elevation, as high as 9,000 feet; and the species in such places seem to be characteristic of the locality. *Aphides* are scarce in such, situations.

Is it possible to introduce these useful little insects as a check to the tea and coffee pests ?

G. P. P.

EXPERIMENTAL SORGHO CULTIVATION IN BRITISH BURMAH.

Thayetmyo District.

The sorgho seeds forwarded to this district for experimental cultivation, the despatch of which was advised in letter No. 1528-175, dated the 3rd August 1878, from the Secretary to the Chief Commissioner, was received in this district on the 12th of the same month. The seeds in quantities of 10 lbs. were distributed for cultivation in the Meaday, Mindoon and Kama townships. To the superintendent of the Thayetmyo jail was given a like quantity.

The experimental cultivation of the 10lbs. of seeds in the Meaday township was sown in an area of land, measuring 12,000 sq. feet. The seed was sown on the 2nd October 1878 in a sandy soil, and reaped on the 28th December 1878. The produce was one basket, weighing 46lbs, and the manure used towards enriching the soil was cow-dung. According to the report of the Assistant Commissioner of Meaday, some of the seeds appeared to have been eaten up by insects, and the consequence was a small outturn.

The unseasonable rains too, had much to do with this poor result. In the Mindoon township, only 8lbs. were sown on the 21st September 1878, and 2lbs. kept in reserve for cultivating during this season, of the 8lbs. were sown in an area of land measuring 1 acre 2 annas. 7 pies, and reaped on the 15th February 1879, the outturn was over a basket, a portion of the seeds were

sown on land on which maize had been grown, and no manure whatever was used to improve the soil. The seeds were sown broadcast.

In the Kama township, the seeds were sown in the months of August and September 1878 in 8 circles, in an area of land measuring 1 acre 9 annas 7 pies. The experiment proved a failure in all except the Natunie circle. The crop reaped here on the 1st January 1879 gave an outturn of one and one-eighth of a basket. No manure was used towards the improvement of the soil in any of the circles. The seeds were sown broadcast.

The cultivation in the jail garden was made on ordinary soil, 10 lbs. were sown on the 7th September 1878, on an area of land measuring 2,520 sq. feet, no manure whatever was used, and the seeds were sown broadcast. No conclusion can be arrived at from this cultivation in the jail gardens since the plants were destroyed by cattle at a very early stage of their growth.

The Burmese are not very favourable towards the cultivation of sorgho as it would seem from accounts given by them, that the new shoots, that spring up after the first crop, if eaten by cattle, will kill them. The "Piyoung nau Isa" which cattle feed upon bears a great resemblance to Sorgho, and it is reported by Captain Cresswell, that the Burman lives in fear of his cattle mistaking one for the other.

PROME DISTRICT.

The sorgho seed received was distributed to each myooke and sub-divisional officer in this district in quantities of 5 lbs. each.

In Pounday, Thaigon and Mahathaman the result has been most satisfactory, the plants growing from 4 to 15 feet in height, and flowered under two months after sowing. The result of the sowing in Showelay township is not so satisfactory. In Padoung the crop is progressing satisfactorily, but owing to late sowing has not attained any height yet. The same as regards Shwédoung.

The Assistant Commissioners of Padoung and Poundav consider that sorgho will grow in any soil provided there is a sufficient rainfall.

HENZADA DISTRICT.

The sorgo seed was distributed to the Extra Assistant Commissioners in this district, and sown by them. No directions however were given to them, and the experiment was rather haphazard in consequence.

Owing to a misleading term in the vernacular letter, forwarding the seed to them, they seemed to expect the crop would turn out a kind of sugar-cane, and their reports merely express their surprise that it is not sugar-cane.

The Extra Assistant Commissioner Kanoung however mentions incidentally that some specimens sown by him reached heights of nine or ten feet. Other specimens sent in from Zaloon were about the same height, and one from the Extra Assistant Commissioner, Henzada, measured 13 feet 3 inches.

The plants appear to yield abundant seed, but before it can be known whether they can be readily acclimatized or not, I would suggest further experiments with the seed yielding by them, to ascertain whether they deteriorate in this soil and climate.

THARRAWADDY DISTRICT.

The sorgo seed received was sown in this district just in the middle of the rains and proved to be a total failure.

This species of seed like that of cuzco maize seed, I am of opinion, will probably thrive on hilly ground when sowed just before the end of the rains. I believe the wetness of season and soil were the sole cause of its failure.

II.

In Madras Colonel A. Drury reports on the experimental cultivation of the *Sorghum Saccharatum* at the Madras Remount Depôt Farm, as follows :—

The first sowing was on the 2nd September 1878, during the rainy season, when 1 lb. of seed was sown in ridges 2 feet apart covering an area of 1,066 square yards.

The first cutting was on the 12th November 1878, or after seventy-one days, and realised...	lbs.	1,087
Second cutting after eighty days	,,	854
Third do, ninety four days		565
Total of green forage	,,	2,506

Besides this, about 170 stems were left for seed, from which 30 lbs. of seed was gathered at intervals.

The second sowing (5th November 1878) was two months later, when there was no rain; the beds were watered by hand but a third of the seed failed, and the remainder was not successful.

The third crop was sown after another month's interval about the 4th December 1878, just before a heavy fall of rain; the seed came up well, and the crop is doing fairly well, but requires irrigating.

The soil on which the sorghum was sown being cold clay, was perhaps not the best adapted, but it had been lying fallow for some time, and was well ploughed and manured before the seed was sown.

The sorghum is an irregular-growing crop, some plants being much in advance of others; it is therefore necessary to cut and come again, or the speedy-growing plants run to seed.

During the rainy season, or with plenty of irrigation, it may be a remunerative crop for cows and bullocks, but I do not think it will ever equal the lucerne as an irrigated crop for horses.

For cattle it may also be stacked and given as dry forage, but then it is not equal to good hay for horses.

THE CULTIVATION AND PREPARATION OF THE SOIL.

AT a recent meeting of the Chester-le-street Farmers' club, Mr. George Burnett, Washington, read a paper on 'The preparation of the soil, and the application of manure for the production of crops.' There was a good attendance—Mr. Chrystal, the president in the chair.

The Lecturer said :—I have chosen for this paper that part of agriculture which relates to the mechanical condition of the soil, and also the question of manures and their application. So interdependent, however, is the science and art, or practice, of agriculture on each other, that it is only by referring to the science of chemistry that we can get a reasonable answer for even mechanical processes. In the laboratory in subjecting certain compounds to analysis, it is customary to reduce it to powder, to add water to it and a little acid, to place it on a sand-bath so that by the application of moisture, heat and the acid, you render very rapidly soluble in water that which is insoluble; so it is also in the laboratory of the soil, we have the heat of the sun, the rains, and in the atmosphere an inexhaustible supply of carbonic acid. The labours of the husbandman supplement this chemical action more or less. By steam, by horse power, and by manual labour, he reduces the soil to as fine a tilth as possible, and as deeply as his resources admit, which then permits the circulation of the air, including its oxygen and carbonic acid, of moisture also which, besides permitting chemical action, is the medium whereby the salts necessary for the existence of the plant are conveyed by the roots for its support. The soils of our country are so varied that it would be a mistake to assume that an invariable rule of culture would succeed in all. Some lands, reduced to a fine tilth, would run together like cement with the first heavy rains, especially if it commences to rain as soon as the work is done, and before it has dried a little on the top. Drainage has done something for this land, and its condition has been ameliorated by deep tillage; a judicious course of cropping helps also, considerably. The contents of our ash-pits are also useful. Still in rainy, and consequently, difficult seasons a farmer may see the season passing away, and he can neither plant potatoes nor sow turnips. What remedy is there here, as the green crop fallow is admittedly the best time for the thorough culture of the soil? We agree, I presume, that land should be ploughed in the autumn, and deeply ploughed also. I have seen lands cultivated, but with some exceptions it is too retentive of moisture, and too much moisture prevents the circulation of the air, and keeps the land cold also; and as the conditions for chemical action are wanting or impeded, the land will not improve in fertility as it otherwise would do. There is also a great natural difference in the quality of soils, salts of phosphate of lime and of ammonia being the most valuable, that the labour bestowed on some soils would produce more crops than double the labour of others. Geologists tell us that this arises from the varying nature of the rocks from which our soils are formed, and that the soil of the Lothians and of the coal measures are a great contrast. However, all soils more or less contain the elements that plants require, and air, water, and the heat of the sun are to be utilised. We cannot increase the surface of the soil, but we can the depth, and thus add to our producing power, with the addition of manures also; and that he who does so in the most effectual manner will best succeed in unlocking the treasures of the soil. Just as the wind and tide are always on the side of the best sailors, so the skilful agriculturist draws most largely on the great laboratory of nature, and renders the richest harvest for the service of man. Well, supposing your land ploughed or cultivated in the autumn, it is seldom, if ever, too dry for that operation. The season is wearing round for putting in green crops; one of two things may likely happen, either the season is a good one or a bad one. If it is a good one, then is little to be said, as the land is speedily bu[illegible] up and your crops put in first-class condition. But

the season is a bad one. We will suppose one of the worst ever known; we cannot cultivate, we cannot plough, nor manure, and, to use a common expression, we had better be in bed and asleep than try to do anything of the kind. But what is to be done—are we to look on with folded arms and see the season passing away? Certainly not. If you cannot plough or cultivate, perhaps it may be grub harrowed or harrowed with the common harrow, or as a last resource, drills may be raised on the stubble furrow. No doubt many will object to this, and say justly what becomes of our theory of cultivation with such an inadequate practical outcome? Well, it is best to keep before us the highest standard, and steadily work to that end. Well or ill put in, however, your green crop is planted and sown, and we have a braird and no summer fallow. This is of some importance. Our attention must now be directed to the after cultivation of the green crop. Land that was not well put away will require a closer attention; the season at some period will be suitable, and such land will require an extra turn with the drill-grubber; and long before the end of the season an experienced eye could scarcely tell in which manner you had arrived at the result. The drill-grubber of modern construction is of strength sufficient to bear the strain of two horses working up to their power. This simple instrument has contributed very materially to successful results in green crop growing. Prepare the land for green crop, it matters not how well, the after cultivation adds considerably to its value, but when badly prepared its after culture becomes all important, so that in the autumn, when the green crops are removed from the soil, its condition is something approaching a deep body of well-cultivated soil, fit for the commencement of the rotation. Concerning the propriety of increasing the depth of the soil much may be said. Few soils are so good but that the subsoil will damage it when first brought to the surface. Yet all soils contain the acids and bases necessary for the growth of plants, in more or less abundance, and in more or less available condition. Some substances require oxydizing, such as protoxide, or black oxide of iron, which, becoming converted into peroxide, is healthy and necessary for plants. Also inert vegetable matter is highly useful in active decay. Carbonate of lime is not assimilated until it is converted into bi-carbonate, which therefore requires the action of the air. The safest plan, in my opinion, for the deepening of the soil is to plough your ordinary depth in autumn, and in spring to go deeper with the cultivator, so that the subsoil is gradually prepared for coming to the surface in another rotation. There is an objection to this course, that by so deeply stirring the soil the surface soil which has been mellowing by the winter's frost disappears to some extent. A remedy for that may be found by cultivating early, so that the beneficial action of frost, or of wet and dry weather may still be attainable; and some lands may be cultivated in the autumn. No doubt, on many lands, in dry seasons to loose the soil mellowed by frost renders the braird of the turnip crops very precarious, and to cultivate deeply when the soil is damp is often the forerunner of a failing crop. But land can be so cultivated under other conditions. If you grow potatoes, the same reason does not apply, nor with bare fallow, if you have any. If the land is ploughed an inch deeper each rotation, I should say it is safe enough; but with confidence in or security from your landlord, and you can afford the outlay, plough the land a foot or more in depth, and in the second rotation you will reap the benefit. To apply manure to the soil is one of the most important duties of the farmer. If he forgot that, he has forgotten everything, for it is the one thing he can the least afford to neglect. The quantity of manure put on the soil is to a great extent, the measure of the crop you receive from it. No doubt the soil yields a portion in proportion to its natural wealth and treatment, skilful or otherwise. From ten to fourteen bushels of wheat per acre, I am told, is something like the product from soils in America, as the result of cultivation without manure. It appears, therefore, that if we wish to grow six or seven or eight quarters of wheat to the acre after heavy green crops, how largely we must be indebted to our manurial resources; and the kind, quality, facility of obtainment, the mode of application are all matters of great consideration. I shall not attempt to go very much into detail, it is not altogether my object in this short essay, but rather to convey to you some leading features as they strike me. I dare say, if we had sufficient farmyard manure, we should be content, but in the nature of things that cannot be. Manure made from cattle fed on turnips, hay, meal, and cake, contains all the elements plants require but the barley and wheat and potatoes have been sold off the farm, and the cattle took their bones along with them to the market. How do we renew those salts so vital to the growth of the plant? You would naturally think we would go where our wheat, barley, potatoes, and beef had gone, to gather back the refuge—precisely what we want. Nothing could be better—nothing so good. Even the bones can again be had ground to powder—thus assisting their decomposition when put on the land and gradually giving out their invaluable quality, and so the chain of animal and vegetable life would be complete. The late Baron von Liebig told us that a pound of bone is equal to a hundred weight of corn; he told us also that if we burn a plant we have in the ash all it ever received from the soil. These small quantities seem easily attainable. Twenty per cent. per ton soluble phosphate spread over three or four acres seems a liberal dose with the addition of farmyard manure; but it requires an abundance for free growth, and it is not clear to me that bone rendered soluble in water by means of a powerful acid, is exactly what one requires; for soils are no doubt wonderful retainers of manures; yet the main drains reveal the secret of the land's management when we come to the analysis of its waters. I have yet to learn that dissolved bones are the best application for a four or five course rotation. There is no more science in the decomposition of dissolved bones than in a recipe for making blacking, as Liebig told us, and he was the originator of the system. I believe manufacturers generally throw in a dash of nitrate of soda or sulphate of ammonia, and sometimes the farmer appears to be astonished at the result. Perhaps the annual application of superphosphates in small quantities may be a judicious investment. Mr. Prout, who grows wheat after wheat in succession with annual top-dressings, appears to have found it profitable. His crops, which I have seen, were very creditable. The inhabitants of towns adopt no means to assist the agriculturist, but the reverse. Their ambition is to have waterclosets and sewerage to draft all refuse to the sea. Now the loss from this cause is incalculable. Were some system of earth closets adopted, fulfilling at the same time all sanitary conditions, as our friends the Chinese appear to be able to do, and the enormous manurial wealth, from the metropolis of England, to small provincial towns, brought back to the land, I should say that our extended commerce is very good, and gold from Australia is good, guano from the Pacific is still better; for a nation with a mighty commerce and starving soils at home is not in a good way and shows a declining patriotism. Were this enormous manurial wealth returned to the soil, another, a greater and more solid form of wealth would be added to our land, and I would make the nation rich beyond the dreams of avarice. The alternative is here also. At an enormous expenditure the sewage of London has been taken farther on before it is discharged into the Thames, and that has only put off the evil day. It is no remedy, even in a sanitary aspect, for as the tide rises it carries it back up to the river, and before it gets to the sea it is again carried back like a churning process or an antagonism of heart, and it is not unlikely to breed a pestilence. With regard to the application of manure, farmyard manure naturally comes first under consideration. It is a common practice in many districts to spread it on stubble in the autumn, and plough it in, and as this is done by many whose opinion on other matters is highly valued, it is entitled to serious attention. The land has a wonderfully retentive hold on all manurial matters committed to its care, and farmyard manure only gives out the food for plants slowly and gradually. By being intermixed with the soil, it is in the best available condition for the use of plants. Manure put on the land in drills suffers from the disadvantage of not being properly intermixed with the soil. The plant has abundance immediately under the roots, but is starved in other directions. But, as you cannot grow crops on a dunghill, so the storing up of manure in drills without due admixture with the soil does not appear to be altogether desirable. Were the manure in drills to be mixed up by means of the drill-grubber, it would entirely alter the matter; but with regard to farmyard manure, I question much that it is practicable. Another great advantage to be derived from this autumn manuring is the great facilities it offers for getting a large breadth of green crop grown and planted in the spring; and this is our great reason which overpowers other considerations, even if it wer objectionable. The advantage of manuring in drills is a practice that ha many advocates, and perhaps the larger breadth of land in the county i so manured. The latest-made manures are made speedily available, an do not, therefore require so large a stock of manure to be gathered u beforehand as the other system; and if the soil and the manure are no intermixed, they come very much in contact, and the effects on the crop ar unmistakable. Indeed, you would naturally suppose that in the earlie stages of the growth of the plant, it would grow quicker than when th roots had to strike a long way to procure their food. In this place I hav no comparative values to offer you as to the best of the two system though, no doubt, some gentlemen here will have something substantial t offer us. With regard to scavenger manure from towns, and which is muc used in this country, I have had some experience of its effects. It ough to be the great manurial supply of this country, but with a complet introduction of the sewage system it would be of no value whatever, and am afraid the quality is deteriorating. I object to ploughing it down o stubble. My reason is, that all manurial matters have a tendency to g downwards with heavy rains. We are told, and no doubt it is true, th in dry weather it will rise again (dissolved in water) by capillary attractio for the use of the plants; but a great deal more rain falls on than rises fro the lands; hence our springs and rivers carrying off at the same ti wealth from the soil. We, however, obtain a portion of our supply ammonia from the atmosphere by rains, especially after intervening fi weather; hence the double benefit of occasional rains. In very ra seasons the crops do not thrive, and the harvest is unsatisfactory. I imagine the food of the plant is continually being carried downwards. F this reason, I would keep all manures as near the surface as possible; a were it not for the escape of the volatile ammonia and the necessity decomposition, they might be on the surface. The mechanical conditi of the refuse of towns enables you to put it on stubble and cultivate it or plough stubble, and apply the manure and grub it in. Drills may manured with it, and you can manure after you have sown your crop, in all cases have good results. I know some farmers prefer this man ploughed in with the stubble in the autumn; but I have tried it, and result was always disappointing to me. I have given you my reason my practice. If I am wrong, I hope you will be able to show me, for are learners. We sip the foam of many sciences, requiring to know th so that we may get a benefit from each. We convey our information fr to each other. We have no trades' union, no protection, no patent righ and we never put up a notice that there is 'No admittance except business.' The application of sewage to the land, I am afraid, can o

be limited, partial, and local. It is not suitable for all seasons or all kinds of crops. Even Mr. Mechi, I should say, would scarcely contend that the irrigation of the soil by means of liquid manure had been successful pecuniarily, and he has advantages that the inhabitants of towns have not, he can choose his time of application, but those must have a constant outflow. However, therefore, you may admire his farm and crops and system, you gradually perceive on reflection that his tank and pipes, hydrant and hose, would cost large sums of money, and the resources of the farm still inadequate to render back sufficient manurial matter to the soil, and that it was not advisable to distribute supplemental manures such as horse and cow manure, dissolved bones, and guano, or even bullock pudding, in that way. The kind of manure depends, to some extent, on the course of cropping, and also on the nature of the soil. Phosphate of lime is as necessary to the plant as bone is to the body of the animal, but some soils require special treatment, and the application of lime is sometimes directly beneficial to the growth of the plant, apart from its chemical action on other matter, in the soil. Land that was once considered unfit for green crops fallow, by good management ultimately becomes so, being ameliorated by the addition of vegetable matter from manure, the roots and refuse of green crops, drainage and deep tillage, it becomes altered both in colour and texture. I have seen the pan at the bottom of the furrow on which horses had trodden perhaps for centuries broken up by steam, and the change for the better in the drier and mellower condition of the soil was something extraordinary. The question to what extent land should be cultivated is an open one, grass land without any cultivation whatever continues to grow good crops without any manure except the droppings from cattle, yet in the preparation of land for turnips it generally receives an amount of labour equal to three ploughings. Mr. Smith of Woolston sets to work with his steam-engine and double mould-board plough and grubber combined, and raises drills from manured stubble. I have not ventured to follow in his foot steps, but must admit his land was in excellent condition and cleanly, and if his land is sufficiently cultivated, and I am not prepared to say it is not, he certainly does it with a minimum of labour. The application of steam to the cultivation of the soil has one great advantage over horse-power, in so far as the power of the steam being transmitted by means of wire rope avoids the trampling that is caused by the feet of horses. I dare say you may expect me to give you my ideas on the comparative cost of steam and horse power. This is difficult; but it is not necessary to have so many operations on the soil with steam, as the treading of horses undoes part of the benefit. The want of success which has fallen to the lot of many companies and even private owners is very little argument against the steam cultivator, for it has not been taken to 'with love.' It is not part of the system, and a due preparation for its introduction, as regards gates, roads, and fields, has not been granted to it. These things are changing a little, but the farmer is slow and sure. Yet we have seen great changes in our times, more, I should say than during the same period in previous history. A law of the ancient Britons compelled every man to make his plough before he should guide one and the driver had to make the traces from withes of twisted willow. So late as 1631 the Irish Legislature passed an Act, entitled, 'An Act against ploughing by the tail, and pulling the wool of living sheep.' It appears the Legislature had discovered that it was a barbarous practice to attach the plough to the tails of the draught animals. Then we come down to the fine figure of Jethro Tull, the father of drill husbandry, and next we have the discovery of drainage, and last of all, when everything is ready, the chemist comes on the scene and unlocks the secrets of the soil and the atmosphere—shows us their beauty and utility. The skilled mechanic is beginning to be skilful enough to help us also, and he got a hint that he would have to do something, his services being required, and he is bettering the instruction. Our farm labourers are getting the qualifications of mechanics. I observed in a leading article in the *Newcastle Daily Chronicle* of November 16th that a short time ago farmers were the resolute foes of education, that we neither cared for it ourselves, nor wished our labourers to acquire it, that in fact a knowledge of arithmetic would ruin them. I should like to know when that time was. But it appears we had some excuse, as we followed a very unlearned occupation. No education, we are informed, technical or otherwise, is required to work the scythe or the sickle. Good mowers were never very plentiful, neither were good shearers. Bad mowers were constantly tinkering at their scythes, and half killing themselves at their work. For to graith his own scythe, to consider the angle at which he bends his back and his height, before he sets his scythe to grass, he is resolving questions in mathematics. Pray what sweep should his scythe have that it may cut evenly from heel to point? Workmen have pride in their work, unless men like this writer are able to destroy it. We have complaints enough of scamp work. If there is nothing to learn in mowing, there is nothing to learn on the farm at all, and no necessity to go to school or college, but we know better. We go to school and college to amplify and confirm our practical knowledge. Education we require, but arithmetic helps us a little. Our men require a knowledge of anatomy, physiology, pathology, and chemistry, and, in fact, the whole circle of the sciences, but they must be able to manage a pair of horses, to stack, plough and mow, and to know when the cow will calve, when the ewe will lamb, and to detect the first symptom of disease in the stock, and know when the land's a brimming. They imagine they know the right angle for laying up ploughing; and if any one thinks he can do better, let him [illegible]. We cannot do without intelligence; and at this day the farm labourers [illegible] country are amongst the best paid of any class of labourers in the kingdom.

DR. VOELCKER ON AGRICULTURAL CHEMISTRY.

Dr. Voelcker delivered, at a meeting of the Midland Farmers' Club in Birmingham, an interesting lecture on 'Agricultural Chemistry in Relation to the Exhaustion and Improvement of Land.' Dr. Voelcker having been introduced to the meeting by Mr. Howman, vice-president of the club, said—It would have been a source of very great pleasure to him if, in giving his address, it had been in his power to congratulate them on the high price of corn, an unusually favourable season, general agricultural prosperity, and bright prospects for the future. That pleasure must, however, be denied him on the present occasion, for he feared he had rather to condole with a good many British farmers on account of the heavy losses which they sustained through no fault of their own during the last and several preceding seasons, and to express his sympathy with them in these hard times, which, although he was glad to say they had not affected his own pocket, had seriously affected some farmers in this country. The present position of the British agriculturist, it could not be denied, was not a very enviable one. What with the low prices of corn, the large importations from the corn-growing districts of America, Australia, and even India; the importation of live stock from America, and dead meat from the same country and from the Continent; the increasing price of agricultural labour, the insecurity of tenure, the difficulties regarding compensation for improvements, and other adverse circumstances, the position of the British agriculturist is not an enviable one, and must be one of continued anxiety—(hear, hear). Still, they must not lose courage; there was the bright side of every thing, and certainly they did not mend matters by looking only at the dark side. The English farmer must be prepared to meet the foreign competition by which he was now threatened, and the question was, how was that to be done? He had thought a great deal on the subject, and had come to the conclusion that the only way to make farming more remunerative—for in all probability they would not get the high price for corn which they obtained in former years—was to grow more corn and every kind of agricultural produce, and reduce as much as possible the cost of production. It was quite true that they had foreign stock imported into this country in large numbers, and as this foreign food was supplied at a very low price, it became all the more necessary for the English farmer to direct more attention than had been hitherto given to the production of meat at a cheap rate. In the present season there had been an abundance of green produce owing to the showery weather, and many farmers would not derive the advantage which was to be obtained from purchased food when given in addition to the natural produce of their land. The low price of foreign grain and cake used for food purposes was most astonishing to him, and it was remarkable that oil-cake, which was at present obtainable at such a low price, was not more freely used. The farmers replied that they had an abundance of green food, and they need not buy any foreign food. Perhaps they would allow him to say that this was just the time to buy food, in the shape of foreign corn or oil-cake to supplement the home produce, and they would find it would return them a high percentage for the outlay; but if they fed their stock principally upon purchased food, they would find the bill of their cake merchant very ruinous. Now was the time to give some additional food in the form of oil-cake. The subject, however, upon which he had come to address them was the chemistry of the soil, and not the chemistry of feeding or fattening cattle. There was a great difference of opinion with regard to what could be got out of land. Some farmers were constantly grumbling about the bad character of their soil: they maintained that it was irretrievably bad, and that nothing could possibly be got out of it. He had heard that morning of land which was so clover-sick that they could not possibly grow anything on it, while others maintained that their land was so rich that they could apply to it no end of nitrate of soda, and grow heavy crops of corn; and, in fact, the more nitrate of soda they applied the heavier would be the crops, and they might go on from year to year without exhausting it. Now, when one heard such diversity of opinion, they generally found that the truth lay somewhere near the middle, and he purposed making some remarks upon what was called the natural fertility and the acquired fertility of land. It was, he believed, an undisputed fact, that all soils had a natural productiveness which they could not permanently raise. By suitable manurial dressing the fertility of land could be increased for a time, but as soon as they left off the application of these manures the land relapsed into its natural condition. They knew that land might go out of condition very rapidly by bad farming, over-cropping, or treatment with improper kinds of manures. They could get land in good condition with tolerable rapidity also, although they could get it out of condition much faster. It must, of course, be the aim of every farmer to keep his land in good condition for his own sake, if not for the sake of his landlord; and while it was quite true that they could not materially increase what he would describe as its permanent fertility. That led him to observe that there was no need for that fear, which was sometimes entertained, that damage would result from relinquishing the usual rotation. When they had to deal with rich clay soils, they could make themselves independent of strict rotation of crops. They might follow a number of wheat crops by barley without materially deteriorating the permanent fertility of the land. That course of cropping would, however, be impossible if it were followed on soils of a naturally low fertility. He was quite certain that if the farmer in future wished to meet the competition of the foreign producer he must give up farming in a mere routine fashion, and be guided by a more rational system of procedure—he must give to the lessons taught by modern science a more

prominent place in his operations, and bring to bear at the same time more the principle of commercial calculation and enterprise—(hear, hear). It was, then, to the progress of science and commercial enterprise that they had to look for a remedy to meet the growing competition to which the British farmer was exposed. As long as there was such a vague notion of what was fertile land, and what was naturally a good productive soil, they could not be surprised that many farmers committed grave errors. There were various reasons for bad farming—some had not sufficient capital, others had not sufficient intelligence, and many did not bring to bear the necessary calculation. They must be aware that fertility of land depended upon some material substances which were found in the soil; and it was quite clear that chemistry threw considerable light upon farming practice. There were some soils extremely poor in particular substances which affected more than others the productive powers of land and they might at once inquire what those materials were. The most important one was nitrogen in some shape or other, either in the shape of nitrates, which were most energetic in their action, but at the same time very perishable, as they rapidly passed into land drainage; or it may be nitrogen in the shape of ammonia, or ammonia salts, or in the shape of nitrogenous matters, which enter rapidly into decomposition and furnish first ammonia and finally nitrates, which, in his view, were most effective plant-feeders, from which albumen, gluten, and other nitrogenous compounds were derived. Available nitrogen in some form or other was a most important soil constituent, and existed in soils in but small quantities. There was another important constituent of the soil, and that was phosphoric acid, which existed in land in small proportions, and in poor soils in very small proportions; so it followed that land which was constantly cropped required to be supplied with manures which contained phosphoric acid in some form or other. Another important constituent was potash, which, however, was found in considerable proportions in the better descriptions of land, such as moist clay soils, with the exception of poor clay soils in the coal measures. In order to give an idea of the poorness of some land, he referred to an analysis which he made some years ago on some very light soil, and which was proved to contain 92 per cent. of sand. Some ten years ago he tried some experiments on Lord Wenlock's estate with a view of ascertaining the best means of growing clover on light land. He found the land extremely poor in nitrogen and potash, and very poor in phosphoric acid. They could form an idea of the poverty of the land from the fact that it contained 92 per cent. of sand and only ·08 of phosphoric and ·14 of potash. The manures used by him were nitrate of soda, sulphate of ammonia, mineral superphosphate, common salt, a mixture of mineral superphosphate and nitrate of soda, and also mineral superphosphate with potash salts. He found that mineral superphosphate, that was, superphosphate made of purely mineral matter without any organic substance, had no effect whatever on the crop and when he used potash alone there was the same result; but when he put the mineral superphosphate and the potash together, he got a most marvellous increase—viz., from 8 tons 5 cwts. 40 lbs. to 13 tons 15 cwts. 40 lbs. The mineral superphosphate alone would not act, because there was another element wanted to bring it into activity, and when that was supplied they saw what a marvellous effect was produced. That showed how necessary it was to notice the chemical qualities of the soil. He had made numerous experiments in which potash had no effect whatever, either alone or in conjunction with superphosphate. Some farmers present might know districts where bones had no effect—(hear, hear). Unless they took into consideration the natural character of the land, they might waste a great deal of expensive manure, but if judiciously applied they would get a very good return for their outlay. Nitrate of soda was a most useful manure when properly applied, but when it was injudiciously used the money might be wasted, and at the same time a serious injury occasioned to the land—(hear, hear). Thus he found in his experiment on Lord Wenlock's estate that nitrate of soda, when applied alone to land, had the effect of exhausting it in one season, and on the other hand, where he used superphosphate in conjunction with potash salt there was a considerable increase in the produce. By the selection of proper kinds of manure they might do themselves good in raising larger crops and leave the land in a better condition, but he would warn them against the injudicious use of nitrate of soda on very light land. There was another circumstance regarding the use of nitrate of soda on light sandy soils: when there were mixed seeds the clover disappeared like magic when it was used, and in the second cutting often not a single plant of clover was left. They could gain a great advantage from the use of nitrate of soda if they applied it to cereal crops in naturally fertile and productive land. He had tried it at Cirencester for a number of years, and found on heavy land an increase which over and over paid for the outlay. He found 1½ cwt. of nitrate of soda mixed with the same quantity of common salt to answer very well, and there they had proof that the very manure which was the farmer's friend mighty when misapplied, become his greatest enemy. If they put nitrate of soda on soils which were specially deficient in the more important mineral and essential constituents—potash and phosphoric acid—they were sure to do mischief, and get the land out of condition; but if they knew how to make the right use of it, which they could only do if they had some knowledge of the chemical properties of the soil, the requirements of our crops, and the best means of supplying them to the land, they would find it of considerable advantage. He would give an instance of the successful cultivation of land not in accordance with ordinary practice, and briefly refer to a novel system of cultivation which had been practised now for thirteen years by his friend Mr. Prout, of Sawbridgeworth. Fifteen years ago Mr. Prout came to him and acquainted him of the fact that he had taken some land, which had the reputation of being exceedingly poor. He expressed a desire to be as independent as possible of stock, and he (Dr. Voelcker) advised him to dress the land well with stable dung. Mr. Prout tried that but gave it up at the end of two years, when he came to him again, and said that it was too expensive a kind of dressing—attended with most inadequate results. He (Dr. Voelcker) suggested to him that probably he had not used sufficient manure, but Mr. Prout replied that he could not afford any more. Upon that he (the speaker) went down to the farm and made a thorough examination of the land, and advised him in regard to certain manures which ought to be put on. Mr. Prout followed the course which he suggested, and it was carried out in a very admirable manner. He had followed it out now for thirteen years with most satisfactory results. Some of them might probably be aware that Mr Prout sold off the whole of his produce. He did not recommend that as a general practice for a tenant, but he pleaded for the intelligent tenant that he should be allowed more freedom of action than he generally possessed—(hear, hear). If he had a lease, and with certain proper restrictions were allowed to do what paid him best, it would be better for himself, and also of benefit to the landlord —(hear). There they had an example of how a tenant might do himself good if he was at the same time his own landlord. Mr. Prout bought his farm, which comprised 450 acres in 1861, at the rate of £33 per acre. He spent upon it another £16 an acre in improvements. The land was of a heavy description and not of a light kind, on which they should not use any nitrate of soda, but it was of a description which he might call fertile in a natural way when properly cultivated. Mr. Prout produced more than from 40 to 50 bushels of wheat an acre, and the great secret of his success lay in the fact that he never stinted the land in artificial manures. He found that on an average he spent from £2 to £2-10s per acre in purchased manures, and what he relied upon were bone dust, superphosphate, dissolved guano, and a moderate dressing of nitrate of soda on the heaviest description of land. Another great secret of Mr. Prout's success was, that the plough was put to his land almost as soon at the crop was off. But perhaps they would allow him to make a little remark in passing with regard to steam-ploughing. Some people had an idea that one advantage to be derived from the steam-plough was that they could go over the ground with it at any time, no matter whether the land was wet or dry. A greater mistake had never been made. They could no more go when the land was wet than they could go with four horses on wet clay land. If they wanted to cultivate clay soils properly, they must not go with the steam-plough on the land when it was wet, or they lost all the advantages of cultivation. It was not merely the horses' feet, but the pressure of the ploughshare that consolidated the land and made it work so badly. The steam-plough did just the same as the horse-plough. If they wanted to derive the greatest advantage from steam-ploughing, they should take the land when it was dry, and keep the clods as rough as possible. The weather would produce the mellowing effect better than any instrument they could use. Therein was one of the great successes of Mr. Prout's system of farming. He broke up his land in autumn before the rains set in; he broke it up as dry as possible, and thus got rid of a great many of the weeds, which could only be exterminated when the soil got caked up. On some of his fields Mr Prout had grown wheat for a succession of years. In some cases he had grown four crops in succession, and had followed those with a crop of barley. In fact, on all his heavy land he would go on growing wheat crops until the land became foul, when he would take as a cleaning crop vetches. Every year he sold off his clover, hay, straw, but nevertheless made a very fair profit—not an extravagant one, but still, by being his own landlord, by being allowed to do what he thought best and in cost judicious, and by having sufficient capital to farm his land well, he realized about £2 an acre. This was no mere theory, because he would give them the returns for several years past. He found that in 1868, Mr. Prout realized by the sale of his crops off about 130 acres of land, £1,726; in 1869, £3,233, in 1870, £4,600; in 1872, £4,743; in 1873, £4,570; in 1874, £4,028; in 1875, £1,518, in 1876, £4,672, and in 1877, 4,451. It would therefore be seen that, notwithstanding the fact of low prices, somehow or other he had succeeded in obtaining the same returns. Hence, if the price of wheat went down, and his returns continued the same, it was to be inferred that he had grown more wheat. And the land, too, was in no worse condition than when he commenced. Indeed he (Mr. Voelcker) had recently examined the soil, and found that if anything, the land was in a better agricultural condition, and he believed that if it were brought into the market at the present time, it would realize more than double what Mr. Prout gave for it. In 1875 the land was valued by a very competent surveyor at £31,000, and now he might venture to say that it was worth £2,000 more, whereas Mr. Prout purchased it for £16,000. In fact, the land was in a better agricultural condition than it was a few years ago. Even last season, which was admittedly a bad one, his sales, exclusive of his clover crop, amounted to £3,820-15s. His wheat averages were £10-2s.-7d. an acre, barley, £9-1s.-6d., and oats, £8-12s.-6d., making his total grain average £9-15s.-3d., which was not bad for the last season. Taking into account the clover crop, and also about 14 acres of tare hay, the whole value of the produce in 1878 was, it was estimated, £1,719. Making allowances for various contingencies he estimated the value of the produce in 1878 at about £4,500 which gave him an average of about £10. The cost of cultivation, including the manure—which, as he had said, amounted to from £2 to £2-10 per acre—was about £8 an acre, so that upon his 450 acres Mr. Prout made a

clear profit of £900. He had merely mentioned this matter as an instance of successful farming—rather peculiar farming, and which he admitted could not be practised everywhere, but which illustrated very forcibly the great advantage of farming when a man was his own landlord, when he had intelligence, when he had capital, and when he had the security that whatever he laid out upon his land would not be taken by another that followed him. He had not in any way exhausted this almost inexhaustible subject of the fertility and improvement of land. There were many means of improving land; but, in conclusion, he would say that what he wanted to impress upon them more especially was this—that it was impossible for a farmer to compete successfully with foreign producers if he followed mere routine practice, and did not take advantage of the lessons which modern science and which sound commercial principles inculcated, or ought to inculcate, upon the agricultural mind—(applause).

NATIVE IRRIGATION.

THE following article from the *Pioneer* graphically pourtrays the imperfections of native irrigation works, and their costliness even when made on really scientific principles.

Ali Mardan Khan may fairly be regarded as the father of canal irrigation in Upper India. His great work was the Ganges Canal, subsequently revised and completed by the British Government, and reviewed by the Sanitary Commissioner. Numbers of people, however, who have become acquainted with the great canal in Dr. Planck's picturesque pages, may be unaware of the existence of similar systems of irrigation all over the country, conducted with private capital according to traditional native methods. Of course, it is not every river that will answer the purpose. The resources of an empire, whether Moghul or British, were needed to draw canals from the two great rivers of the Doab; and many of their affluents, though of comparatively inconsiderable size, are beyond the control of private means, because they have no well-defined channels, but persist in wandering at their own sweet will through sandy wastes. Masonry dams or even rubble weirs, are no light matter in a country which does not produce a stone to throw at a dog; especially when the river has to be kept well in hand, and brought up to the obstacle properly, or it will refuse the leap, and go shying off into the drifting desert on either side. Thus it often happens that streams, tractable enough as regards the volume of water, and flowing through rough thirsty tracts, proclaim themselves as useless for irrigation by the gleam of white sandhills from afar. But there are others of a more kindly nature, flowing between unmistakable banks of solid earth, bordered with trees, dispensing shade and greenness instead of barren glare. It is these which are turned to account by the agriculturist, to bring the beloved water to his crops. With amateur engineering, and levels worked out by rule of thumb, he will contrive a system of water channels which, when in full operation, shall protect the harvests of fifty villages. Unfortunately, its operation is very uncertain, from variety of causes, and the result not unfrequently is that villages assessed at irrigation rates, are in want of water every other year.

To begin with, the dam is a great trouble. A stone weir, such has one commonly sees above watermills at home, is effectually prohibited by nature. A brick weir would be far too expensive. The only alternative is an embankment of earth. This, again, cannot be made everywhere; one has to choose a spot where the soil contains a maximum of clay and a minimum of sand; and then, with plenty of straw and a fair proportion of "ladies" in the centre of the bed (such is the the native name for the equivalent of what the military mind would call fascines) one may hope to build a dam which will hold up many goodly feet of water through the scorching months. But in order that the water may gather head, it is needful that the dam be built immediately after the close of the rains. That would be a sufficiently simple matter, is the building of it were any one man's business, and if that man had no lack of capital and public spirit for the job. In reality, these dams are usually the joint property of the landlords of several adjacent villages, most of whom are impecunious, and every one of whom is quite willing to leave the initiative to all the others. If there is a man of means and energy among them, he is regarded with suspicion, as desirous to deprive his partners of their immemorial rights. These rights, again, are too often of very uncertain value. They are commonly of the nature of dues from all the villages receiving water from the dam, or the sharers are entitled to free labour from those villages in building and repairing it; but in practice neither the rupees nor the men are given with any regularity. There is, in fact, no obvious method of enforcing rights like these. The revenue courts cannot in strict legality take cognizance of them, and the civil courts are expensive and ill-adapted to such causes. Uncertain and indefinite as they are, however, their possessors cleave to them jealously; and any attempt to interfere with them is sure to cause trouble. When at last all difficulties have been removed, when the *vis inertiæ* of the native character has been overcome, and the committee have resolved to make a beginning of their dam, fresh grounds of debate are sure to arise in the course of the work as regards the quantity of earth to be contributed by each member. One man is to undertake one end, his partner the other, while two more divide between them the two slopes of the middle bank, and all are bound to lay on their due proportion of earth, as measured by the square wells in the dry bed where the necessary excavations are made. All this causes delay, and does not tend to increase the solidity of the work. Sometimes the dam will be scamped with light soil instead of clay, and the tail of the rains will sweep it away, leaving the committee too exhausted or too disgusted to build another. But supposing that they have gone honestly and zealously to work, and that a good strong dam crosses the river-bed, and defies casual floods—there still remains the question of the water which should be behind it. The dam may be admirably calculated to stop every drop of water that reaches it; but this quality cannot well be tested if all the water in the river has been stopped already by a dam higher up. In fact, the villages all along the banks shew their appreciation of a stream of this kind by damming it every four or five miles; and though there is plenty of water for all the dams, if they are only made in time, yet when the business is postponed, the odds are increasingly in favour of the villages higher up the stream as against those below. There are, indeed, recorded stipulations by which every dam is entitled to draw upon the dam above it; but in a late season it is more than doubtful whether such drafts will not be dishonoured. A liberal discount in the shape of cash down, is not unfrequently demanded in such circumstances; and illegal as the claim is, the wiser course often is to comply and save the harvest. There is not always time to await the result of a reference to the revenue court; much delay is involved in the calling for reports and the recording of evidence; and after all, the conclusion arrived at is likely enough to be in favour of maintaining the *status quo*, for the letting out of water has been a dangerous business since the days of Solomon. An inspection of the river would clear up all doubtful points; but every one acquainted with district work knows that it is not always possible for an officer to visit a given spot at a given time.

Postulating the dam in the first place, and the water behind in the second, there remain the questions of the temporary distribution and final disposal of the precious. It is surprising what a quantity of water one of these dams will hold up. Below is the river, deep sunk between its banks; above is a little lake of clear water, reflecting every tree on its borders, and making a fair and cheerful prospect far and wide. But be the prospect never so wide, the people of the watered villages will wish it wider. They are always crying "more, oh more, we are thirsty yet!" They lament the good old days when the water was up to a man's waist in their streets. They are eternally pointing out impossible altitudes as the regular recorded flood level. At the same time, they do not take the slightest pains to expedite the raising of the level by confining the stream, or by giving a scientific frontier to their watery possessions. Their object is simply to accumulate as much as they can, regardless of the fact that the more distant villages are vainly waiting for their channels to be filled, while the water which should rise and replenish them is wasting itself in holes and backwaters spreading laterally instead of rising vertically, and adding square yards to its surface, instead of the few all-important inches to its depth. And when the channels do begin to fill the water is checked in its course by a variety of impediments. The main arteries are merely natural creeks twisting about in the lovely fashion peculiar to the Indian nullah, and deep enough to swallow up a small river before a drop can reach the fields. The channels made by man possess indeed the main virtue of being true to their levels, but they are too commonly choked, and even when in the best repair, it is part of their original plan to expand into lakes every quarter of a mile or so, each of which takes a couple of days to fill, and when filled is of no particular service, except as a wallowing place for the buffaloes. So much for the distribution, from which it is easy to see how much chance the outlying villages have of getting water, when quarrels or carelessness have delayed the building of the dam. The final disposal of the water involves some points which carry us back to the beginning. The most elementary acquaintance with practical hydrostatics will enable one to grasp the fact that an earthen dam in the rains must do one of two things,—it must either hold the water up, or break. Overflow is impossible. Generally speaking, the dam breaks, because it has not had money enough spent on it to stand the increased pressure. But it would be rash to infer that this restores matters to their pristine state, and that the cycle of dam-building, dam-keeping, and dam-breaking can commence *de novo*. On the contrary, the released river usually revenges itself upon its gaolers by scooping a huge hole under its prison wall, which effectually prevents any similar structure next year upon the same foundations. In this way, in the course of a dozen years, the dam will be gradually driven down the stream, leaving a wilderness of holes, excavations, and remnants of old banks, in which the water, coming down from above, may waste itself at pleasure. These accidents might be avoided if the centre of the dam were based upon a solid foundation of good puddled clay, with rubble over it, extending as an apron on either side for some yards; but such an expedient is out of the range of native foresight. The other plan is to build a dam which shall not break; and sometimes if the rains are reasonable, this will succeed for as many as seven years together. Of course, escape-channels must be provided at the sides, and these, unfortunately, have a habit of usurping the rights of the river, which finds itself some fine morning high and dry, while the treacherous escape channel has marched off with all the water, and is announcing itself to the country-side as the original river out on tour. When the next dam comes to be built, a new site must be chosen, and the riparian villages will have to lament so many acres of land cut up and thrown out of cultivation.

One would like to point a moral from all this. The most obvious moral is the uselessness of expecting from the natives of India either continuity of purposes, or unity of action, or expenditure on distant objects. If these people will not exercise ordinary care and prudence in using the gifts of Nature, they must suffer for it. If a settlement at irrigation rates is not enough to remind them that they must provide water for their fields, it is their own look-out. Nevertheless, something might be done for them in the way of instruction. It would cost canal officers little trouble to make themselves acquainted with the

systems of their native rivals, and they might often be able to give valuable advice which, backed, if necessary, by the collector's order, would make all secure for the present and prevent misdirected labour and expenditure in the future. Again, it might be found that the landowners concerned, or at least some of them when enlightened as to their real interests, would be willing to make an effort towards placing the whole system on a satisfactory basis once for all, by building a masonry weir or dam with spacious sluices for the flood waterway. The cost is of course the great impediment; but there are rules under the Land Improvement Act, which could not be more usefully applied than to cases of this kind. The advantage of the canal officer's advice in this respect would be two-fold;—the zemindars would get a rough estimate of the extreme cost, and they would have the way smoothed for their application for assistance under the Act. All this could be managed by a couple of visits to the spot in the court, of a year. Meanwhile, the matter would be kept in notice for future occasions, and especially against the contingency of future famine. Nothing could be more suitable for the employment of famine labour than works of this kind. They would be close to the labourers' homes. They would furnish work to many hundreds for several months; for besides the building of the dam, and the rectification of the wasteful gulfs behind it, there would be many miles of straight orderly conduits to be dug, in the place of the present tortuous and haphazard channels. To one and all concerned, it would be a labour of love. Not the meanest basket-bearer but would understand and appreciate the value of the work. The quantity done would admit of the strictest measurement, and the work would remain useful for ever, for if the Indian labourer has any glimmering of science, it is in the matter of levels and watercourses. Much might be saved in supervision, for once the lines were marked out by the engineer, the zemindar could safely be trusted to see that the work was not scamped, and thus the principle of local action could be enforced. Local responsibility might also be insisted on, at least to ascertain extent, by making the zemindars contribute a portion of the expenses, whether by immediate payment or by annual instalments upon the revenue. The point is one worth bearing in mind against years to come. It would be an improvement to substitute anything for the plan of throwing shovelfuls of earth by the roadside, or, as has despairingly been suggested in some quarters, digging a great hole, and filling it up again until prices mend.—*Ceylon Observer.*

NAGPORE MODEL FARM.

HALF YEARLY REPORT.

(By Captain F. B. Morris, Superintendent)

THE farm, it is known comprises some 460 acres; but the whole of this area has not this year been retained in our hands and cultivated. Sixteen fields containing 127 acres have been leased out to cultivators. The soil of these fields is a very shallow black, with out crops of moorum; they will bear only the very lightest of crops; they are at a distance from the steading and the more important parts of the farm; and as the farm has only 15 pairs of cattle, the farm lands were too extensive to permit of all being well and deeply cultivated. It was therefore determined to leave out these fields and concentrate attention on the remainder of the farm. The Chief Commissioner was good enough to sanction the proposal. It may be remarked that in 1873-74, these fields were also let out to cultivators from whom an average rent of Re. 1 per acre was obtained. Since then these fields have been deep ploughed, and the consequence is that cultivators have been most anxious to obtain them. An average rent exceeding Rs. 1-10-0 per acre has been obtained, and some of the fields are rented at more than Rs 3 per acre. These rents greatly exceed the rent for land of similar quality in the neighbourhood, and they prove that the cultivators clearly see the advantage of deep ploughing. That they do not practice it themselves they explain by pleading their poverty, and the weakness of their cattle. The fact is they do not care to take the trouble.

The fields on the farm too which have not yet been completely levelled suffered also greatly from scouring. Certainly the monsoon was not favourable to the kharif crops. Some sowings were completely washed away and a luxuriant crop of weeds choked others. Cotton and jawari chiefly suffered. In the surrounding country the results of the continuous, and heavy rain were the same. The cotton crop it is estimated will not exceed a 6 anna one, and the jawari a 12 anna one, at the most. On high lands the jowari is better, but in the best lands the weeds sprang up so rankly, and the continued rain so long prevented all attempts at weeding that the cultivators in many cases finally abandoned all thought of weeding in despair, and many fields look as if the weeds were the natural crop, and the jawari a fortuitous growth. In another way the late rains prevented the preparation of the soil for the rabi crops, and the fields were very late prepared and late sown. In fact some fields put under wheat were not sown till the beginning of December.

In all, about 210 acres are devoted to what is called the commercial farm; that portion in which ordinary crops are grown in the ordinary manner, but with greater care than is the practice with ordinary ryots. Of this area, about 102 were put under kharif crops, and the remainder under rabi. To take the kharif first. About 21 acres were put under Hinganghat cotton, and 60 acres under jawari; the other fields being sown with tur. All these fields have at some time during the last 5 years been deep ploughed—so the soil has been well turned over. They were this year prepared for the kharif sowings by being well 'bakared'* in June, and the beginning of July. By the 17th July, all the fields were sown down, and it was fortunate that that was accomplished so early, for the rain when it did come down in July was against field operations. But the cotton fields could not stand the heavy and continuous rain. They lie sloping northwards the water scoured over the soil, and not finding an outlet turned the fields into a morass; the excessive damp killed the young plants; one after another they pined and died. Two out of the three fields under cotton were, on the utter failure of the crop, again ploughed out, and prepared for linseed in September, the sowings being completed in October.

One or two of the fields under jawari which greatly absorb moisture also suffered from excessive damp. As already mentioned the heavy and continuous rain prevented hoeing and weeding, the result being a poor crop.

The other fields under khatif crops did fairly well, still they too suffered from want of hoeing and weedings at the proper time, and from the absence of sunshine. When the weather cleared at the end of August and beginning of September, there was so much work on hand that the lost time could not be made up for. What could be done in the way of weeding while also preparing the fields for the rabi, was done; but on the whole only fair crops can be expected. The 'tur' promised very well until cloudy weather in October did some damage bringing out caterpillars, but a change of weather occurring about the middle of November, the plants picked up again and the weather since has been very favourable. The mode in which these crops have been cultivated does not differ materially from the native methods. The 'bakur' used on the fields is, however, somewhat superior to the ordinary native one, and more attention is paid to hoeing and weeding. Sowing is done somewhat earlier than the ryots are accustomed to and in the sowing of jawari a superior seed-drill is made use of. It leaves the seed somewhat nearer the surface and enables it to come up earlier. The amount of seed sowed, per acre, is also very much less than with native cultivators. Only 9 lbs. are used to their 40 lbs.

In sowing cotton too less seed is used than by the ryots, about 12 lbs. to their 16. The 'dhaoras'* used also of a superior make.

In sowing 'tur,' advantage is taken of a drill, which has four drills in a line each 18 inches apart, and by that means the seed is much more rapidly put in. In other respects, however, innovation has not been attempted.

Of the area under rabi sowings,—15 acres were sown with linseed,—17 with gram and 45 with wheat.

The fields could not be got at properly till September, when they were turned up with the English horse hoe, and by the middle of October most of the early rabi fields were ready. The linseed was at once drilled in. Unfortunately rain came down on the 21st and 22nd of that month, preventing further sowing and sweeping away the young seedlings that had come up. The fields had to be re-sown. The re-sowing was completed by the 1st November, and the crop promises well, gram was put in at the same time as linseed and is also doing well, though in the beginning of November the cloudy weather was somewhat against the plants.

The wheat sowings were got in between the 12th and 21st November, a late date, but this season unavoidably so. Fortunately the seed has come up well and the fields promise well. Besides a more careful preparation of the land, there is this difference between the native treatment of these crops and that pursued on the farm,—that the amount of seed sown per acre both in the case of wheat and linseed is considerably less than the ryots sow; in the case of wheat, 40 lbs. to their 80 lbs. or more; in the case of linseed 9 lbs. to their 18 or 20 lbs. The seed drills are also somewhat heavier, and the sowing is somewhat deeper. In the case of gram on the other hand a somewhat larger quantity of seed is used.

The present weather is very favorable to the rabi crops, and if it continues a good harvest may be expected.

I turn now to the fields in the Experimental Farm.

In fields No. 6 an acre planted last year with arrowroot is under jawari 'ganari,'† the field was manured in the previous year and was deep ploughed. The jawari was sown on the 20th July, and it promises to turn out exceedingly well: this portion of the field is well levelled and the manuring and deep ploughing naturally tell.

Another acre on which ginger was grown in the preceding year was put under Hinganghat cotton, the seed being sown on the 29th June after careful preparation of the soil; but whether it be the result of the season which has been so very unfavourable to cotton, or of the exhausting nature of the ginger, the cotton crop is poor.

A third acre in this fields was put under 'Jugdam'‡ jawari succeeding cotton. The land was 'bakared' and the sowing favourably completed; but the plot is not quite level and part of the seed was washed away.

Another field No. 8 was deep ploughed and 'bakared' and sown with jawari; but the heavy rain washed away great part of the seed and the outturn will not be good.

In field No. 9, 1 acre under peas in the preceding year was levelled and manured, and after careful preparation was put under chinur § 'dhan. The crop got on well till the end of August, but the September rain levelled the whole field and the outturn was consequently not good. It is possible that the 'dhan' should be put out later in the season.

A second acre which had been under Guinea grass was devoted to Carolina rice. By the end of July, it was seen that the young plants were languishing, and a top dressing of cowdung manure was applied. The

* Prepared with the "bakar," a kind of harrow.

* 'Dhaora', Indian hoe.

† Ganari' meaning sweet, a superior kind of jawari

‡'Jugdam', universal or common, an inferior kind of jawari

§ Dhan, rice.

monsoon rain however appeared to be too much for this crop, and the yield was below the average. Subsequently this acre was in October, after the rice was harvested, top dressed with cowdung manure, cultivated with the horse hoe and well 'bakared' and sown with lucerne grass of which the seed was got from England. The seed was got in by the 21st November; it germinated well and the grass is doing well under irrigation.

The acre on which the crop of chumur 'dhan' had been taken, was also in November ploughed up with the English plough, well 'bakared.' Sewage manure was applied and turned up with the ridge plough. Garlic and onions are being put down.

Two acres were levelled and manured and ploughed up with the English plough during April and May,—and as soon as the monsoon set in, planted with Guinea grass,—a top dressing of sewage manure as being applied and the plants are healthy and promise well.

One more acre ploughed and manured during April and May was again ploughed and manured in November, and has been under Guinea grass also, but in this case the ridge plough has been used so as to try the ridging system.

In field No. 10 there are 3 acres of sugarcane, two acres of ginger and 1½ acres of turmeric, the field had been carefully ploughed and manured. The sugarcane was planted somewhat late, the planting not being finished till the middle of April, and the plants suffered from the great heat of May and June and the very heavy monsoon. Caterpillars too did some damage and the result of all is that the crop is only a fair one. The ginger and turmeric failed because of the very great moisture.

In field No. 11 an experiment with Indian corn, and one with Banni cotton both failed, perhaps because the crop followed too quickly on sugarcane which had been taken from the land.

A small experiment with Rhea was not very satisfactory.

A considerable portion of this field is devoted to experiments with rabi crops. Part of the plot on which Indian corn was tried was on the failure of that crop again ploughed up with the English plough, manured with cowdung manure and wood-ash, turned up with the ridge plough and planted out with potatoes in the latter part of November. These promise to come up. Another half acre was after being ploughed and manured, divided into beds and sown with Italian red clover. The seed was imported from England, but it has not germinated properly.

One acre after being ploughed and manured in April and May, was again in October gone over with the horse hoe, top dressed with cowdung manure and sown in November with indigenous wheat. The seed was selected from the best samples obtainable in the bazar and the field promises well. Another acre having been similarly treated has been sown with English wheat. Half the field has been irrigated and the other left unirrigated but the seed would appear to have been poor, it has not germinated properly.

Another small experiment with potatoes in field No 17, failed.

Fields, Nos. 17, 20, 23 and 21, which are not suitable for cultivation have been turned into a forest plantation. Some seedlings were planted out, and seeds of various kinds sown. Some have come out—the experiment has just begun.

In fields 35 and 37 two acres have been planted with oranges and plantains which are treated in the ordinary manner. They are coming on well.

The foregoing remarks show what has been going on at the farm during the last six months—what crops are being grown, and what experiments have been tried. At this time the kharif crops have not yet been reaped, the actual outturn cannot therefore be given and statement regarding them must lack precision.

A DISCOVERY IN SUGAR.

IF statements embodied in a report by the English Secretary of Legation at Washington on 'Sugar Production in the United States" which has just been issued as a Parliamentary paper, come to be verified in actual experience, the sugar trade of the world is likely to undergo some very important changes during the next few years. The consumption of sugar in the United States is very great in 1876, a year when severe commercial depression had reduced it considerably below the average of the previous three or four years, the total consumption was close upon 1,430 millions of lbs. in addition to nearly 49,000,000 gallons of molasses. Of this enormous quantity of sweet stuff, more than 1,277 million lbs., or nearly 88 per cent., was imported, and it may therefore be said that practically the United States are at present dependent for their sugar supplies on foreign countries. The great bulk of the imported sugar—about eighty per cent., or just over a thousand million lbs. —comes from Cuba: the rest is obtained, in much smaller and comparatively insignificant quantities, from Porto Rico, other Spanish possessions, the French, Dutch, and British West Indies, Brazil, British Guiana, and the Sandwich Islands. The average value of the annual import of sugar into the States during the past few years has been nearly £17,000,000 sterling—that is including the duties imposed by the American Government, which form a considerable proportion of the total sum. These facts and figures indicate that the United States are among the largest consumers of sugar in the world.

It is only natural that a nation which possesses so vast a territory, presenting such varied climatic conditions, should endeavour to produce for itself an article of such primary importance as sugar. Attempts of this kind have been made in different parts of the Union for a long time back and have not been unattended with success. In 1861-2, the production of cane-sugar in Louisiana was more than 500 million lbs. and reached, in fact, to considerably above one-third of the total consumption. But this extensive industry sustained a terrible blow during the war, and its recovery has since been so slow that in 1876-7 the production was under 200 million lbs., or barely 12 per cent. of the total consumption. Various reasons exist for doubting whether it will ever be restored to its former dimensions. The true sugar-cane, *arundo saccharifera*, the plant which is cultivated in Louisiana, is only indigenous in strictly tropical regions, and the narrow fringe of territory on the Gulf coast, where alone it will grow at all, is extra-tropical. Although fresh cuttings were continually imported, and nothing that human skill and enterprise could effect was neglected, the sugar-cane has never been really acclimatised in Louisiana, and has invariably and rapidly deteriorated. Moreover, a large area of the best sugar-growing lands in the State is exposed to the annual inundations of the Mississippi. Hundreds of thousands of acres of such lands are said to be at present lying waste through the breaking of the levee, and it has been practically proved that resources of the planters, and even of the State itself, are not equal to the task of constructing embankments which will permanently keep the river within its proper bounds. Thus sugar-culture in Louisiana must always be carried on under conditions of difficulty and expense, which will act as effectual limitations to its developement. Attempts have been made in various parts of the Union to produce beet-sugar, and much capital and effort have been expended in this way, but thus far it has not been found possible to obtain beet sugar of good quality, and in sufficient quantity, and at sufficiently low cost, to take the place of the imported sugars produced from the tropical cane. Furthermore, beet can only be grown for sugar in the Middle and Northern States, and will, it is said, "only yield sugar remuneratively where the summer rainfall is equal to that of spring, and the natural peculiarities are not unfavourable."

But recently a discovery has been made by a Mr. Stewart, of Murraysville, Pennsylvania—who has devoted his attention for some years to the chemistry of saccharine juices—which, if it be verified in practical experience, will in all probability convert the United States from an importer into an exporter of sugar. This discovery is nothing less than the fact that excellent sugar can be obtained from the stalks of maize or Indian corn, and from sorghum, or Chinese sugar millet. Maize, it is scarcely necessary to say, is one of the chief agricultural products of the United States: it is brought there to greater perfection than anywhere else in the world; it can be reared in almost every State of the Union, and the yield, especially in some of the rich prairie soils of the Western States, is so enormous that stalks and grain have often been used as fuel because there was no means of profitably disposing of them otherwise. The sorghum, which has been acclimatised in America for nearly twenty years, is a still hardier plant than maize, and Mr. Stewart says that "the climate of the whole territory of the United States south of Alaska, where the soil is not barren and the moisture insufficient during the summer months, is adapted in various degrees to its growth." Thus the chief obstacle which has always stood in the way of the economic culture of the sugar-cane in Louisiana does not exist in regard to either maize or sorghum. Again while the sugar-cane has to be propagated by cuttings, both maize and sorghum are propagated by seed, which can of course be grown at a comparatively insignificant cost, and in both the juices mature in a much shorter period than in the case of the true sugar-cane. What is known as "starch-sugar"—a very different and greatly inferior substance to crystallised sugar—has been obtained from maize for some years past, and an inferior kind of sugar has been extracted from sorghum in China from a very remote period; but from neither plant had a sugar which could compete commercially with the product of the *arundo saccharifera* been obtained before Mr. Stewart undertook the scientific investigation of the subject. The result of that gentleman's experiments, which have been carried on with great care and completeness for two years, is to show that crystallised sugar, equal in quality to the best that is imported into the United States, can be obtained from both sorghum and maize in large quantities. Mr. Stewart puts the average yield at 1,800 lbs. of sugar and 41 gallons of molasses per acre; but with careful cultivation and judicious manuring, he is of opinion that 2,000 lbs. of sugar and 66 gallons of molasses per acre might be obtained. Besides this there is to be taken into account the green grain of each plant, and a large yield of green fodder, while the refuse of the manufacture will suffice, if returned to the soil, to keep it in good condition. The process of manufacture, which Mr. Stewart has explained in detail—reserving only for the present the secret of the chemical process which has made it successful—is more simple than that employed in the case of the true sugar-cane, and much more economical than that which is necessary to extract sugar from beet.

The practical value of Mr. Stewart's discovery and the accuracy of his statements seem to be beyond question. Mr Drummond, our Secretary of Legation at Washington, whose report on the subject embodies the facts given above, says he has tasted sugar extracted from corn stalks, and that "it is very sweet and well crystallised." He also mentions that a farmer in Maine having made some experiments in sugar production from maize, estimates that the yield of sugar from one acre of that cereal will give as much profit as the produce of thirty acres of wheat. Even supposing that this is too sanguine an estimate

it is still evident that a new productive industry of enormous value and importance has been brought within the reach of American agriculturists. Mr. Stewart calculates that two per cent. of the area now devoted to the cultivation of maize will be sufficient to supply the whole home demand of the United States for sugar. If this calculation at all approaches correctness, it may reasonably be anticipated that in very few years foreign producers will no longer find a market for their sugar in America; and even if the maize and sorghum sugar is not found capable of competing in the European market with cane sugar, the diversion to that market of the large quantities heretofore consumed in the United States must have the effect of greatly reducing the cost of the article to the consumer. As to the consequences of the new discovery on the beet-sugar industries which have been laboriously built up in France, Belgium, and Germany, on rather artificial foundations, it is perhaps premature to speculate. But it may be worth while to remember that maize can be grown in Southern France, in Italy, and in other parts of Europe, and, moreover, that it is indigenous in India; and if the new process proves as successful as it is said to be, there is no reason why its application should be confined to the United States.

BARRON'S TRANSPLANTING MACHINE.

THESE machines were originally invented by Mr. William Barron (of the firm of W. Barron and Son, landscape gardeners and nurserymen, Elvaston Nurseries, Borrowash, Derby) in the year 1831, then and for many years gardener to Charles, the fourth Earl of Harrington, and for whom he laid out the extensive and unique grounds at Elvaston Castle. It was by the aid of these machines that the wonderful effects were there produced in an incredibly short space of time, which afterwards became the admiration of all who had an opportunity of visiting the gardens at Elvaston. The first trees operated upon were four large cedars of Lebanon, and the following table will give the respective dimensions of each when first transplanted until 1871, which was the last time they were measured.

Date of removal.			Height.	Circumference of stem.		Height.	Circumference of stem.
Feb.	1831	No. 1	28 ft.	4 ft.	1871	77 ft. 10 in.	7 ft. 2 in.
"	"	" 2	32 ft.	3 ft.		81 ft. 8 in.	9 ft. 8 in.
"	"	" 3	35 ft.	8 ft.		76 ft. 4 in.	9 ft. 6 in.
Nov.	"	" 4	33 ft.	6 ft.		58 ft. 10 in.	9 ft. 9 in.

It may be asked why Nos. 1 and 4 did not increase in the same ratio as Nos. 2 and 3. The cause is easily explained, *viz.*,—No. 1 was planted on the south side of the grand avenue, which runs from west to east, and was shaded by tall trees; Nos. 2 and 3 were planted on the north side of the same avenue, consequently they were fully exposed to solar action; No. 4, after it had been planted a few years (in consequence of surrounding objects), had its branches foreshortened several feet (its branches being fifty feet diameter); thus the want of solar action in No. 1, and the shortening of the branches in No. 4, materially lessened their elaborating powers. From November, 1831, up to March, 1851 (when the demise of the fourth Earl of Harrington caused such operations to cease for a time), many hundreds of large trees, some of great age and size, both deciduous and evergreen, were brought from surrounding counties from ten to thirty miles, and with uniform success.

For the last twenty-five years Messrs. Barron and Son have kept a number of these machines, of six different sizes, for hire, which they send out with one or two experienced men, according to the size of the machine required, at a fixed charge per day. They have been employed in almost every county in England; in Wales Scotland, Ireland, and on the Continent. A remarkable example of a tree moved under great disadvantages may be seen at Swithland, near Leicester. This tree, a large Scotch fir, fifty feet high, was removed in July, 1868. It was seen by thousands of visitors who attended the Royal Agricultural and Horticultural Societies' Shows, when they were held conjointly at that time at Leicester. It was brought upon a No. 2 machine a distance of eight miles into the show yard the week before the show, and stood there the whole of the show week following; it was again removed five miles and planted. It still lives and thrives, after being *eleven days* upon the machine, exposed to a cloudless sky and a broiling sun during the whole of the time. Numerous other examples may be seen at Millichope Park, Shropshire; Lockley, Welwyn, Herts; Drayton Manor, Tamworth; Dorfold Hall, Cheshire; Whitbourne Hall, Worcestershire; Winslade, near Exeter; Crofthead, near Glasgow; Lower Grounds, Aston Park, Birmingham; the Royal Botanic Gardens, Kew; and at many other places of note too numerous to mention.

A tree being about to be lifted, say forty or fifty feet high, the diameter of branches will about determine how far it will be necessary to trace the roots, which must be carefully denuded of soil up to the size of the mass of soil to be removed, say ten feet by nine. Under this ball and under the centre of the tree a drift must be made two feet wide under all the roots; this being done, two sets of best 3 in. red deal planks, 11 in. wide, must be passed through, standing not less than 9 in. beyond the ball at each end. Resting on these at each end an end plank of the same strength, with one of the top edges bevelled, must be passed under the ball; that done, two more side planks must be introduced under all the roots, these to rest at each end of the end planks. By this means the tree, with its large mass on soil and all the roots within remain undisturbed, the machine being then put to the tree, it is then raised by strong rollers at each end by means of lever bars and ratchet wheel; these are placed across the trussed beams of the machine. Should guy ropes be necessary, which they will be if the tree be tall and have a heavy top, they should be put on before the centre drift is made. On each roller is fastened the two ends of strong tar rope, capable of bearing more than half the weight of the tree. After it is raised, strong chains, suspended from the beams, are passed under the centre planks at each end to carry the whole weight, also four corner chains, suspended from the beams, are fastened to the four corners where the side and end planks cross each other. By this means the tree is kept steadily in its erect position.

When the tree reaches its destination great care must be observed in getting the under planking out without breaking the ball of earth or otherwise injuring the roots. It will always pay in having large trees removed to have an experienced man to conduct operations, otherwise failures may be expected.

Trees of immense size, far too large for any machine, have been transplanted most successfully by this firm, under Mr. Barron's personal superintendence. In several counties (*e. g.*, in Kent) trees weighing about thirty tons have been transplanted; in Surrey, in the latter end of July and the first week in August, just when in an active state of growth two remarkable cedars of Lebanon were removed a considerable distance and transplanted; both are growing as if they had never been removed. One was over 50 ft. high, circumference of stem 6 ft. 10½ in., and weighed over fifty tons. The largest one was over sixty tons, and of the following dimensions.—Height, 47 ft. 6 in.; diameter of branches, 59 ft.; circumference of stem, 11 ft. 6 in., and at 4 ft. 8 in.; above ground it was 10 ft. 9 in. The solid mass of soil removed with the tree was 18 ft. long, 15 ft. 6 in. wide, and 3 ft. 7½ in. deep. The whole was taken up an inclined plane one in eleven, carried on rollers, and moved by powerful machinery.

FRENCH AGRICULTURE.

FRENCH agriculturists are divided upon, and becoming somewhat distracted about, the question of free trade *versus* protection. In certain regions of France, the price of wheat varies fr. 18 to 22; consequently it no longer pays to cultivate grain at this price. It is also a truth, that putting a tax on American corn—for the States supply two-thirds of that imported—will not remedy the evil, for foreign grain, owing to expenses of production, &c., being less, could still successfully compete with home grown, also with grain and if a tax was levied, the consumer would have to pay dearer for his bread, and the proceeds of the impost would go, not into the pockets of farmers, but into the coffers of the State. If the culture of wheat does not pay, farmers must try the production of meat, but above all, pursue more advanced systems of tillage, notably the usage of commercial manures, irrigation and the employment of machinery: the latter is more than ever necessary at present, when the population tends to emigrate to the manufacturing centres, attracted by higher wages. France has not much more than commenced to lay in her necessary supply of agricultural implements. In order to encourage the extensive use of machinery, workshops, with able mechanics, are to be organised to be ready to execute repairs.

M. Goffart, the discoverer of conserved green forage for stock, is in the habit of publishing annually a statement of his experiences; this year his remarks are not less valuable, because they are an exception to an interrupted success, the system has not been at fault, but the experiment has suffered from bad weather and questionable seed. His neighbours are not more fortunate. While 40 tons per acre of green maize were yielded, in some cases not twelve were obtained. This latter return is simply ruinous when the heavy expenses of tillage and manure are borne in mind. The choicest seed maize comes from Nicaragua; but it never arrives in time, and is injured generally by the weevil. New York supplies the next best seed, provided it be transported in barrels, to avoid heating; failing both, the ordinary horse tooth maize is to be preferred. It is no longer a question that the best method to preserve, as well as to employ the forage, is to cut it before treading it into the trench or pit. A machine worked by hand is not to be thought of; a cutter driven by two horses ought to chaff the green maize at a cost of 6 sous per cwt., while an engine will do the work for two-thirds less. It has been ascertained, that a trench eight feet wide, and covered with earth, will lose 20 per cent. of its

contents, while the loss will be only nominal if the trench be made double the width. Another point to be noted; there is a growing disposition among farmers to employ nothing but this trench forage all the year round. Generally one man, at fr. 2½ per day wages, is allowed the care of twelve head of cattle, fed on beet, turnips, hay, &c., to cut the roots, and provender. M. Goffart requires only two men, at the same rate of wage, to take charge of eighty head of stock fed on the pit rations.

Dr. Estein, of Bonn, draws attention to some singular facts, connected with dairy stock, that is, regarding cows viewed as machines for transforming raw material food into milk. He lays down that the milk-yielding quality of cows is not peculiar to any race, so much as that the mean yield between breeds is different. A good milker may be common to any race. It appears that a M. de Kappen, near Paderborn, registers every fortnight the weight of each animal, and the quantity of milk it has yielded—testing thus the ratio between secretion and flesh. Now the digestive aptitude is proportional to the live weight, and the function of the mammiferous organs to the quantity of nutritive elements conveyed to them by the circulating blood. The average weight of thirty cows is 11½ cwts. and the daily yield of milk over 11¼ quarts, or 773 quarts per year, for every 2 cwts. of stock. Now one animal with a live weight of 11½ cwts. yielded 1,286 quarts of milk per 16 stones weight, while another of 13¼ cwts. gave but 398 quarts, per the 16 stones. Here the evidence is striking that the difference depends not on race, though the herd is Dutch, but on the formation of the mammiferous organs. Further the relation between the yield of milk and its richness augments with the abundance and superior quality of the ration; the appetite of the animal thus becomes the test. Now as it clearly requires more food to support an animal of 13¼ cwts. and yielding less milk than one of 11½ cwts., the latter must be the more remunerative machine for transforming food into milk.

Street sweepings form a manure of an uncertain importance, but in Paris, that which is produced in the vicinity of the markets is more valuable. At Dunkirk, the refuse of the streets is mixed with stable manure and sea-sand, the mass being daily wetted with urine and feculent matter; its wholesale price is frs. 2¼ per cubic yard or ton, the contractors re-selling it to farmers for frs. 4. As a general rule, not more than 50 per cent. of street manure is valuable. Professor Heinrich of Rostock, has experimented with six different kinds of nitrogenous manure on rye, the soil operated upon being deficient in azote. The same quantity of nitrogen given in spring to the several plots, under the form of fish, guano, powdered horn, blood, and nitrate of soda, have produced the same effect; but have been less efficacious, when in the form of sulphate of ammonia or powdered flesh. The influence of all the manures was excellent on the grain, thus contradicting a common belief that it is the straw which is influenced. When there is too much fat in an animal manure, its action is diminished. In the present experiments, nitrate of soda proved the best manure, and in addition, was the least costly. M Ladureau's experiments with flax are interesting; the most lucrative yield of flax is that from a manure uniting azote, phosphoric acid, and potash; the fibre, though not so abundant, will be of superior fineness. Nitrate of soda does not produce much effect, flax requires very little soda, but much potash, and it has not the power to replace, like beet and some other plants, potash by soda. In the north of France and in Belgium, the plan is therefore bad, which consists in dosing, more or less strongly, with farm-yard manure, guano, oil-cake, animal refuse, and similar nitrogenous manures, soils intended for flax. When the land is of ordinary richness, 2 or 4 cwts. of the salts of potash and of magnesia, sown in spring, will suffice.

It is anticipated that the new commercial treaties will give an impulse to the cultivation of hops in this country. France has about 9,000 acres under the crop, which sells at frs. 70 the cwt. Twenty years ago the price was from frs. 200 to frs. 400. Cabbage is liable to a well-known disease in the roots, called club root · it is not very general in France, but in the neighbourhood of St. Petersburgh, it is a veritable plague. M. Weronin has devoted three years to the study of this disease, which he calls "hernia"; it is produced by a microscopic parasites, and develops with greater rapidity in moist, than in dry soils; radishes and turnips are liable to be attacked by the parasites, which, quitting the excrescence in the root, seek refuge in the soil, till occasion offers to feed on another root, irrespective of age. Burning the diseased roots, and changing the crop for a few years, are the proposed remedies.

"REBOISEMENT."

Of the slipping in of the sides of ravines M. Théiu gives a graphic account in the French review. The undermining process, begun in times of heavy floods, often ends, he tells us, in embracing the entire slope of a mountain, and the pictures fully bear out his statement. The torrents of France, according to these authors, generally present three features: first, the cone of dejection, at the point of the egress of the stream from the mountains; secondly, the main channel of its course, which is usually in narrow ravines with high precipitous cliffs; and lastly, the catchment basin, where the cliffs open out and form a wide irregular amphitheatre. It is here that the waters collect which feed the stream, and it is upon the fact whether the slopes of this amphitheatre are clothed with woods or that depends the violence of the torrent in times of heavy rain or rapid thaws. If bare, the area simply forms an immense funnel which drains off the waters as they fall, and converts a watercourse into a raging river.

The operations proper to "reboisement" consist therefore, (1) of planting and grassing the slopes of the catchment basin, with subsidiary works to render the former possible and effective; (2) of direct impediments to the violence of torrents, in the shape of dams, piling, &c.

Especial pains appear to be taken with the planting. If the slopes on which the plantation is to be formed are irregular in appearance, and cut up by deep watercourses, the first thing done is to reduce them to a plane surface. A model is devoted to the illustration of this subject. The ridges are hacked down, and the hollows filled up, or propped with sustaining walls or piling. The slope generally is also supported with piling and fascine work. A favourite plan is to use truncheons of live wood for piles, and interwine them with willow branches fastened into the earth, thus producing a living fence. The ground may then be considered as ready, and the young trees are either planted or sown. In either case it is usual to sow grass seeds at the same time, in order to increase the stability of the soil and afford shelter to the young plants.

In the case of very steep ravines the ground is marked off in little terraces or stages inclined slightly inwards, in order to retain the water, and these are planted with trees on their outer edge. The trees are hard woods of two or three years of age, and are planted thickly, so as to touch one another. This method has been found perfectly effective in fixing such places. An improvement on it has lately been adopted in the case of the stiff lias clays, which are the most untractable of all the soils that the forester and engineer have to deal with. The plan is, instead of making a regular terrace or stage, to make but an incipient one, or mere edge. It is inclined inwards about two or three in ten, and faced off vertically on the upper side. The plants are then inserted as before in the groove thus formed, and covered with earth from the stage immediately above. This is termed the *cordon* system. It has the advantage of not requiring any pile-work to support it, and of not altering the appearance of the slopes, as in the terrace system. Slips from above are also less frequent when this method is employed, as the water is not liable to penetrate the ledges so much as in the case of the terraces. In the intervals between the lines of stages rich grooves are sown together with the seeds of coniferous trees.

Of the dams and other direct obstacles raised to avert floods it is hardly necessary to speak, save that they are of all kinds, from rustic work to finished masonry. That in the model of the Bourget torrent before us cost, we are told, £620. It is 23 ft. high and about 5 ft. 0 in. broad at the top.

THE FIBRES OF BURMA.

British Burma imports annually fibres of one kind or another, products of the vegetable animal kingdoms, together with their manufactures, to the value of about 5 million sterling. Of gunny bags alone, a million and a half are imported, besides raw silk and others. Considering the natural advantages of the place, this import trade is not a little anomalous. Few countries possess so many and different kinds of fibre-yielding plants as this one, and yet local trade is indebted to Bengal for jute and jute-fabrics, to India for cotton, and to a number of other places for fibres and textile manufactures. The genera of the vegetable kingdom famous for their yield of fibre exist here largely. On the highways, and byeways, in the jungle and the fields, such as *Sida, Urena, Hibiscus, Abutilon* abound. Rangoon and its suburbs can boast of a number of them, all growing wild. Notwithstanding this mine of vegetable wealth, little has been done for its development. Jute cultivation was tried some time back, but failed. The causes, however, for this are so well known, and easy of removal, that it is a reproach to local enterprize nothing has since been attempted in the line. But leaving jute out of the question as already noted, the country is rich in other varieties of fibres, and a visit to the Phayre Museum will convince the most sceptical on this point. The specimens there exhibited are all the yield of indigenous plants, and those chiefly of the Malvaceous order, the order to which the gaudy shoe-flower and purple-eye cotton belong. They are all cultivated with the greatest facility, and as readily propagated. With ordinary care and trouble, a field could be raised without much cost of time or attention, and to very great profit. The humble weed *Sida*, with its tiny, pale, orange bloom, to be met with on the sides of the dustiest roads, yields one of the toughest fibres in existence, and those from *Urena* and *Abutilon* are long, flowing, and glossy, like jute.

The members of the orders named have in addition this advantage—they arrive at maturity one after another at intervals sufficiently removed to permit of a field being worked up well after a growth before another is put down. In this way, with a little foresight and provision, produce might be obtained nearly all the year round, and the loss from keeping labor unemployed reduced to a minimum. The manipulation of fibres from most of these is neither difficult nor arduous; and all things considered, it does seem a very great pity

that such a promising source of natural wealth should, up to this day, remain undeveloped. The want of labor is accountable, before all others, for want of progress and improvement in this direction, just as it is accountable for the backward condition of most other local industries and manufactures. Indeed, the advance of the whole country is stayed on account of the poverty of the labor market. Until the labor-question is solved, there is no hope for profitable development of natural resources; and very little for the opening out of the country in general or the prosperity of its trade and manufactures. To be fair and truthful, however, it must be acknowledged the question has not been neglected by the local administration. Mr. Thompson, than whom a better revenue officer would be difficult to point to, saw and appreciated the difficulties in the way, and did not spare efforts to secure labor for the local markets. Unfortunately, however, for the country Mr. Thompson was not free to do as he liked. The ninteen lakhs of rupees given him during the Madras Famine, to utilise for purposes of State Immigration, were so restricted by conditions that from the outset, he saw little, if anything, would ever be got with the unusually liberal grant. Mr. Aitchison, who is more of a statesman, sees the difficulty in the matter as indeed all who have studied the country and its interests do, and from him the province may look for larger, broader, more statesman-like measures. The labor difficulty forms one of a cluster lying at the root of the prosperity of the province. These happily solved there is no limit to the advancement of this portion of her Imperial Majesty's Empire. What are needed are energy, resolution, common sense and liberal outlay together with experience. In Mr. Aitchison we have one who admirably satisfies all personal requirements, and in the matter of outlay he has the will if he has not the power. It rests to a great extent with the Supreme Government whether the province shall have capital and labor. The present Chief Commissioner may be trusted to do all he can; but in consequence of financial arrangements, he is unable to spend public money as he pleases beyond a certain limit. Imperial sanction is necessary for all considerable outlays, and to secure matters of imperial importance outlay must needs be of an imperial kind. All that the ripe experience and wisdom of nigh a quarter century of official life, in one of the most trying and responsible positions under Government, may be expected to achieve, Mr. Aitchison may be confidently trusted to perform. But he can no more open out the country without funds than the children of Israel were able to manufacture bricks without straw. In aiming to place the land policy on a popular yet safe basing, the Chief Commissioner is in the right way of removing half the difficulties in the matter of labor and capital. All that is needed under the present *régime* is sufficient funds, and with these there is no reason why the province should not before long take rank as chief amongst the Indian pro-consulates.—*Weekly Review.*

DR. AITKEN ON THE CHEMISTRY OF AGRICULTURE.

WE reproduce the following from the *North British Agriculturist*:—

A resumé of second of these series of lectures on "The Chemistry of Agriculture" was delivered by Dr. Aitken in the hall of the Highland and Agricultural Society:—Dr. Aitken referred to what had been explained in the previous lecture—that plants were living organisms requiring food, that they were able to derive that food from two sources—the air, which contained carbonic acid, water, and ammonia, or the products of its oxidation; and the soil, which also contained these, and which specially contained the mineral constituents of plant food. Plants, like animals, breathed oxygen and gave out carbonic acid, but those which had green leaves were able to decompose carbonic acid in their chlorophyll cells, forming therein the well known substance starch; and eliminating oxygen in the process. This was possible only in sunlight. The starch became soluble, and passed from the chlorophyll cells to all parts of the plant, taking part in the formation of wood. The energy required to perform this work was derived from the sun and stored up in the plant, and this stored-up energy was able to be transformed into active work by animals who used the plants as food. He next proceeded to explain the part which nitrogen played in forming the tissues of plants. He showed that though plants were surrounded by an atmosphere consisting mostly of nitrogen, yet they were not able to make any use of it. Only combined nitrogen, either in the form of ammonia or nitric acid or their salts, or nitrogenous organic bodies, was capable of being assimilated by the roots and leaves of plants. The nitrogen taken up by plants was mostly converted somewhere in their organism into a highly complex organic substance called albumen or protein, which abounded in young, tender, and growing parts of plants. This it did in combining with the starch or other carbo-hydrates present in the plant, water and carbonic acid being eliminated in the process. It went on in darkness as well as in light, and was not dependent on the immediate agency of chlorophyll. The air contained traces of ammonia, and the leaves of plants could absorb it. Rain also washed it out of the air and carried it to the earth, where it soon became converted into nitric acid by various processes, the most interesting of these being that recently discovered by Schloesing, *viz.*, the vital activity of minute germs living in the soil. Nitric acid was converted into nitrates, and in that form it was absorbed by the roots of plants. The amount of ammonia taken up by plants from the air was exceedingly small, and that carried to the earth to be absorbed by their roots was limited, averaging probably not more than from five to ten lbs. per acre annually. This was not sufficient to supply the wants of agriculture, which took nitrogen from the soil in the form of crops to the extent of forty or fifty lbs. per acre annually. Long-continued experiments by Lawes and Gilbert showed that continuous cropping without the application of nitrogenous manure produced with most crops a meagre harvest. Hence the necessity for the application of nitrogenous manures in order to secure large crops. The lecturer next discussed the various sources of loss and gain to the atmosphere of combined nitrogen, and at the close of the lecture drew an instructive picture of the correlation of animal and plant life in the earth. The lecture was illustrated with diagrams and experiments, and was listened to by a large and attentive audience.

ALOE-FIBRE FOR PAPER.

MR. CRUICKSHANK, Collector of South Arcot, has brought to the notice of the Madras Government a very interesting experiment in paper-making conducted under the auspices of the Tehsildar of Cuddalore. Samples of the paper have been submitted to Government, and it is stated that the cost of making the 7½ quires was Rs. 2, "but this cannot be accepted as the real cost, because, if more fibre had been given, more paper could have been made with the same labor. The manufacturers say they can make paper from the aloe at the same cost as from hemp, and that the paper made from each could be sold at Rs. 2 per ream. The Tehsildar thinks that a ream of paper made from the aloe might, if the paper is brought into use, be sold for 1 rupee 12 annas." The Tehsildar, C. Vencataramiah, writes:—"The papers manufactured from the aloe fibre are far superior to the papers manufactured from hemp, and they appear to be finer and more durable than any other papers of country manufacture. Ink does not sink through them, and they are not liable to be torn when folded. The following is the description of the several processes adopted for the manufacture of aloe papers. A certain quantity of aloe leaves were collected and made to soak in water for fifteen days. On the 16th day they were beaten on a stone and washed in water when the matter covering fibre is separated. The fibres thus secured were dried in the sun and a quantity equal to six pounds in weight were then cut into small pieces with a bill-hook and thrown into the tread mill for the purpose of being powdered. Three men were employed to tread the mill while one had to sit near the pit into which the fibres were thrown to re-thurst into it the pieces that escaped the operation of the mill. The beating continued for six hours, and then the powder was taken out of the pit and placed in a heap on the pavement, and pouring water over it, two men trampled on it for about one hour. These two persons, putting the powder in a cloth, washed it in a running stream. The powder was brought again to the pavement where mixing in it chunam dissolved in water it was placed on the pavement. It was allowed to remain in the same state for four days, and on the 5th day the heap was spread over the pavement in the sun. An hour or two afterwards it was again beaten in the mill and again washed as on the previous occasion. Chunam water was again mixed with the powder and left in a heap on the pavement for another four days. The same operation was repeated for the third time and left in a heap for four days more. On the 5th day of the operation for the third time the powder ball was washed and dissolved in fresh water in a tub and papers were then manufactured and dried up. Next day the paste was applied on both sides in order to render the paper to bear smoothening. Six pounds of aloe fibres produced about 7½ quires of paper, and I herewith submit the specimens as ordered."

The Board of Revenue think the sample of paper forwarded by the Collector "is far superior to ordinary country made paper, and, if the material were worked up in England with proper appliances, a really good article would probably be produced. The Board would suggest the preparation of half a ton of fibre to be sent to Messrs. Routledge or other paper manufacturers for experiments." The Madras Government, however, do not see the object of preparing fibre and sending it to Messrs. Routledge for experiment in England. "What is wanted is to develop local manufacture. Endeavours should be made to find some one to make the paper in Madras; it might then be tried in the public offices. Possibly, the manufacturer of the specimens forwarded by the Board might be able to make a quantity sufficiently large to admit of its quantity and cost having a fair trial." We think the Government should themselves see that this experiment has a fair trial. As for the Tehsildar who has made this interesting experiment, he is not even thanked for his exertions.

JUTE IN THE UNITED STATES.

THE Americans are making active efforts to grow jute extensively, and its culture, a matter of prime necessity there, promises to become a great element of prosperity and riches. When we consider that in 1870 the United States raised 1,500 millions of bushels of cereals, this necessitated an enormous number of sacks, the value of which, if made of jute, was estimated at 100 millions of dollars, and a far higher sum if made of cotton, flax or hemp of European growth. The country itself is far from producing anything like a sufficient quantity of raw material for bagging. The Americans now import about 78,000 tons annually of hemp, jute, and other fibres, of the value of 2,500,000 dollars. Many of the States, the southern States especially, are now turning their attention to the culture of hemp and jute, and factories are to be established for making it into bagging.

At Charleston a company has been formed with the special object of entering upon this manufacture. They have bought in the upper part of the town large ware-houses, and have converted them into factories, well fitted. In order to commence work, 300 bales of jute were bought by the company in the States of New York and Ohio, and they have distributed seed freely to sixty or seventy planters, so that if the protective duties which press on the import of this fibre are not reduced, as they are expected to be, in a few years, the culture of jute will be an accomplished fact in South Carolina. Under the auspices of the Department of Agriculture at Washington, experiments have been made in South Carolina, Florida, Georgia, Louisiana and Texas; these have shown that the hemp will grow well wherever the climate is warm and humid, and the soil is of a light sandy clay, in fact, wherever there is an alluvial soil.

Much of the land at present devoted to rice is perfectly suited to jute; the resulting benefits would be immense, and the first outlay insignificantly small. To prove the great importance of the culture of this fibrous plant, let us see what has been done in Bengal. In 1828 less than 40,000 lbs. of this Indian hemp was exported; in 1860, 1,000,000lbs. of fibre and cordage was exported, and 300,000,000 lbs. of fabrics. In 1872, the shipments were 700,000,000lbs., of which 300,000,000 went to England. In 1876, the exports from Calcutta were 5,206,570 cwts. of raw jute, 19,258,250 gunny bags, and 8,532 pieces of cloth, the whole valued at £3,294,521. The land under culture with jute in Bengal exceeds 900,000 acres, and more than one million of inhabitants are employed on it. One plantation alone employs 4,500 work-people, and manufactures more than thirty millions of pounds of jute into gunny bags or sacking.

VANILLA.

THE vanilla bean is the produce of an *orchid* creeper which although growing from the root, is a parasite, as it will grow even when cut from the root, for it takes it substance from the tree around which it clings by means of its thousands of fine tendrils. Like all parasites there are trees which are particularly adapted to its support. They are planted about ten feet apart, in rows, at the foot of small trees which are left in clearing the land. They begin to bear the third year, and in favourable years give from 400 dollars to 1,000 dollars per acre. No cultivation is needed but to cut down the grass and weeds, no ploughing or digging being necessary. The bean is often gathered in September and October, but if left till the end of November or December it comes to perfection. It is then gathered carefully and spread out in the sun on mats, if the weather be favourable, but if otherwise it is placed in ovens, which processes change the colour from a pale green to a rich brownish or purple and at the same time develop the oil, which on pressure exudes from the bean. They are then packed in blankets while warm and put into large tin cases to go through a sweating process; again put in the sun and again in the blankets until they attain the proper colour. They are then placed in a dry room upon shelves made of some open material, so that the air can circulate around and under them. This evaporates all the watery part of the bean. When sufficiently dried, they are put into large cases ready to be assorted into sizes and qualities. The person that raises the beans seldom cures them, for that requires a good deal of care and special attention. There are about fifteen different classes, but they are sold by the packers at one round price. The people will work only about one hundred days in the year, which provides them with all they need, and as they will do no more, there is very little increase in the production of anything. When the beans are assorted they are tied up neatly in bunches of fifty beans each, and packed in cases often holding from two to three thousand. These tin cases are lined with tinfoil, and a ticket placed on the lid giving the quality, size, and quantity. Some five or six of these tin cases are put into a neatly made cedar chest, which is sometimes lined with zinc and hermetically sealed so as to prevent moisture from getting to the vanilla in transport, which would ruin it. These cedar cases are then sewed in mats, and covered with a coarse bagging, to avoid the danger of transportation on mules. In this manner all the Mexican vanilla goes to places of sale in Europe and the United States. Formerly France was the great market for Mexican vanilla, but the enterprise of some of the American merchants has diverted the trade to New York, which is now the great depôt of vanilla.—*Edmund Johnson, Tampico.*

SEWAGE CULTIVATION.

THE following letter on the utilization of sewage from Mr. Alex. Aird, of Danzig, to Mr. J. J. Mechi, should be of interest to many of our readers :—

"I was indeed glad to read your last letter to the *Times* knowing so well, from my own experience, that your repeated appeals for the prevention of the present enormous waste of manure must in time be fully recognised and appreciated. Here, with our Danzig Sewage Farm, we are in our seventh year, and with, I am happy to say, in every respects most happy results. As you will remember, the land we own is or was, of the poorest possible kind—pure 'dunen' sand—and our crops this year, chiefly wheat, barley and rye, have exceeded, both in quantity and quality (as attested by the market agents) those grown on the richest land in the province.

"*During* the past year our farm has been visited by individuals and deputations from all parts of Germany, Russia, &c., and in every case our visitors have expressed their opinion that the system and detail arrangements are 'convincing.' I regret to add that not one Englishman has paid us a visit. I fear the reason is the general opinion that Danzig is a very disagreeable town on the Russian frontier, whereas Danzig can only be described as 'Nuremburg-on-the Sea,' surrounded by the most charming hills and wood scenery. That our arrangements here have proved successful, you, as a practical man, will understand from the fact of our having closed a similar contract with the municipal authorities of Breslau (270,000 inhabitants), we undertaking the laying out of the irrigation lands (3,000 acres) and taking the same in lease for a term of 12 years, on terms satisfactory both for the town and ourselves.

"In Berlin the sewage irrigation system has already proved a very grand success, and deservedly so. All vegetables are sold at a much cheaper rate than formerly, and arrangements have been made in the interests of public health to supply the poorer families with pure milk at a nominal rate. I can safely say that all the larger towns in Germany are preparing to carry out the same system, the German Government having wisely determined to prevent in good time the pollution of their rivers. I read all the English publications I can obtain on this subject, and am almost regretting the 'bungling' (I fear this is the only word to use) that takes place. Most of all do I regret, and this I consider really a disgrace to England, that the Metropolitan Board of Works has so entirely 'shifted the question.' A very moderate outlay would have sufficed to prove results which would have long since established the truth you and I already recognise as to the national benefits to be derived from 'utilisation of sewage.'"

SULPHUR FUMIGATION.

MR. HUGHES writes as follows to the *Ceylon Observer* :—In reply to your communication of yesterday, respecting the preparation of a fuse which on being ignited will evolve thick clouds of sulphurous anhydride without flame, I beg to say that so far as I am aware sulphur when used in fumigating purposes is generally employed alone. Sulphurous anhydride or sulphurous acid fumes, or gas as it is sometimes called, is one of the most powerful reducing agents known, and I apprehended that a mixture of any carbonaceous material would have the effect of very considerably reducing the chemical results of fumigation. Dense volumes of smoke consisting of minute particles of solid carbon with some carbonic oxide and carbonic acid fumes would certainly not increase the chemical action of the sulphur fumes.

There is no doubt that fumigation is the most perfect form of applying sulphur, but the action though uniform and energetic is not so permanent as in the case of the external application of the flowers of sulphur to the leaves, for as soon as the umbrella covering is taken off the rush of air will remove all the existing fumes, which will be carried away by the wind.

Fumigation must assuredly be conducted with much more caution than the comparatively simple process of dusting with sulphur.

It will be necessary to ascertain by practical experiment the quantity of sulphur that may be burned under each tree, so as to destroy the fungus without affecting the fruit, and having had the coverings made of uniform size, it will only be necessary to have the respective fuses of sulphur of a certain definite weight and so remove all possible danger from carelessness on the part of the coolies. The more simple the process the less danger of mistake.

It would be desirable to have the coverings whitewashed with Colombo lime in order to protect the material from the effect of the fumes, which in a short time would soon render them rotten, unless in some way protected from the sulphurous anhydride. It has struck me that whitewashing with lime the stems of the trees as well as the primary branches might as a separate treatment be used in the early stages of leaf disease before the leaves are visibly affected, as appears to be the case from Mr. Morris' very interesting report of experiments at Wallaha published in the *Overland Observer*.

As regards the preparation of a fuse I am of opinion that sulphur will be more effective when used alone, and that a convenient and accurate way of using it would be to obtain sulphur specially rolled in lengths of from 3 to 4 inches and about and ½ inch diameter. These pieces resembling very small cigars could be fastened in slits, let in at the top of sticks which latter could be used again for several subsequent batches of trees.

Perhaps Mr. Brock, the well-known pyrotechnist, could suggest some special fuse which would not detract from the merits of the sulphur fumes. It is quite possible to prepare a fuse that shall give dense volumes of smoke, but I scarcely think that such smoke would be an advantage in fumigating. In conclusion I would strongly recommend great caution in using sulphur by means of fumigation, as otherwise very serious damage may result to the crops.

THE GARDEN.

A WRITER in *Der Deutshe Garten* states that the Imperial Library of China contains 15,000 works on the cultivation of flowers and botany, whereof about 500 are devoted to the rose alone. Such quantities [illegible] roses are grown in the Emperor's gardens that the [illegible] essence prepared therefrom annually brings £5,000 [illegible]ury. Talking of Chinese botanical literature, rem[illegible] Japanese have already adopted the botanical [illegible]ognised in Europe and other countries, and [illegible] of the flora of Japan to which the Latin name[illegible] exceedingly good.

THE Superinte[illegible] of the Government Gardens at Bangalore reports as foll[illegible] the vanilla plants in the Gardens :—The vanilla plant[illegible]imentally cultivated in the Lal Bagh, have not been so h[illegible] after as they were prior to the drought of 1877. The f[illegible]it crop of 1878 fell off, the plants abortively ripened and were in consequence useless. The plants are now showing symptoms of returning health and vigour, there is a good show of blossom at the present time (4th March) and I am not without hope that the vanilla may yet give satisfactory results. Sixteen plants were put down in a "mango tope" last September, and these are growing vigorously now. There are about 200 spare plants in the nursery.

THE net cost of the Botanical Gardens at Mussoorie and Saharunpore is Rs. 25,000 per annum, but the valuable results which they yield, more than compensate for such an apparently large outlay. We are glad to hear, therefore, that a proposal for the reduction of expenditure made some time since by the North-West Provinces Government has since been withdrawn. The Saharunpore garden under the superintendence of Mr. Duthie, whose attainments as a botanist and agriculturist are well known, has been making rapid strides in the direction of improvement. The botanical collection has been considerably increased, and it is hoped that in course of time it will possess one of the finest collections in India. Vegetable seeds and plants and trees are supplied from this garden in large quantities and with satisfactory results. The Mussoorie gardens are worked in conjunction with those at Saharunpore, and are used for the collection of botanical products which will not thrive on the plains. A ready market is found there for all garden products, and as considerable improvements are in contemplation, it is reasonable to suppose that their sphere of usefulness will be much extended.

DRIED VEGETABLES.—We copy the following from the *Journal of Horticulture*, as a matter of general interest to all who may desire to have a supply of fresh vegetables out of season without resorting to the use of those which are preserved by, in many instances, objectionable and unwholesome processes :—'We have recently tested some dried vegetables, which have been submitted to us by Mr. Theodore Alkemade, 3, Melrose Terrace, Stamford-road, Tottenham, who is now on a visit to this country from Nordwyk, Holland. The vegetables have been dried by a process which has been adopted by the Alkemade family for upwards of a century, and they are in great repute on the Continent. During the drying process "nothing," says the proprietor, "has been added to the vegetables, and nothing, except water taken from them ; and when cooked they assume their normal colour, and, to a large extent, their flavour." This we have found true. The vegetables we have tried are scarlet runners cut ready for cooking ; dwarf kidney beans uncut ; and broad beans, small seeds of the Mazagan type. In appearance the dried vegetables are uninviting, being small, hard, and shrivelled, but after being soaked in water for six hours their change is marvellous, their colour returning and their bulk increasing in a very marked manner. When cooked we were surprized by their excellence. While not being equal to freshly gathered vegetables, they approach them far more closely than we expected, and sufficiently so to be acceptable as a change when fresh vegetables of the same kinds are not obtainable. The vegetables, such as the cutting of scarlet runners, have hitherto been prepared by the hand, a necessarily tedious and comparatively expensive process, but machinery is now projected for their preparation, which will no doubt reduce the cost. Although as vegetables out of season, they are not particularly costly now, yet if they can be cheapened they will almost certainly be in large demand for consumption both on land and sea. It may be noted that dwarf kidney beans, popularly termed French beans, are not usually sliced on the Continent ; but varieties such as the *Princess* are grown, and the pods are cooked whole after the beans are formed in them. The dried specimens are of this kind, and on that account are not, we think, likely to be popular in England.'

CARBOLIC ACID IN THE GARDEN.—The very general employment of carbolic acid for sanitary purposes induced a correspondent of the *Vienna Illustrated Gardener*, who relates his experiences in that journal, to try whether it might not be applied with equal advantage in some of the many diseases to which vegetables, as well as flesh, are heirs. He first experimented with a solution of one part of the acid in twenty parts of water, which was allowed to stand for twenty-four hours before being used. By that time a layer of fat or oil had appeared on the surface, the contact of which with plants speedily destroyed them. This was consequently withdrawn by means of a pipette, and the clear fluid below alone used. This proved an equally dangerous application, for some beds of savoys and radishes, which were watered with it in order to free them from ground fleas with which they were infested, were totally destroyed by it. A weaker solution, consisting of one part of acid in fifty of water proved scarcely less injurious to vegetation. The application was now tried in the still more diluted form of one part in a hundred, the supernatant oil being carefully removed before use. In these proportions it answered admirably as an insecticide, without causing the slightest injury to even the tenderest plants. A single application effectually freed the beds from ground lice and similar destructive vermin. A very small quantity introduced into an ant-hill so disturbed its busy inhabitants, that, contrary to all the habits of these insects, they abandoned their pupæ in their hurried flight. A cherry tree whose ripe fruit afforded a favourite hunting-ground for these ants was at once protected from their visits by a slight application of the solution to its stem, though they returned to the attack in four or five days when the pungent smell of the acid was lost. Their further depredations were once for all checked, however, by a girdle of cotton-wool impregnated with the strong acid being bound round the trunk. Many other varieties of insects were kept at bay, or driven from their haunts by the same means, which also formed a most valuable protection against mildew, with which the rose and peach trees in the garden were sadly troubled. In one instance, a rose-tree which had borne no flowers for five previous years in consequence of mildew attacking the young stems of the buds immediately they were formed, was observed to bear a magnificent crop the first season that a timely application of the solution was made.

ROSE GLOIRE DE D JON.

WE have seen this rose grown upon its own roots, but it is generally budded or grafted upon some strong briar as a stock for it. There are several varieties of briars, even amongst those found growing wild in the hedges, woods, and uncultivated places ; some are smooth-skinned, having few thorny hooks upon their stems. Such may prove suitable for some of the weaker and less vigorous-growing roses, but they do not answer well for the Gloire de Dijon ; one cannot give it a too vigorous stock to grow on. In budding, select for it the briars having the roughest skins and the strongest thorns, and then one may reasonably expect to see a healthy plant full of vigour, and yielding a pretty general and continuous succession of flowers during summer, and much later in the autumn than most other kinds. We have seen this rose growing in a greater variety of positions than any other rose that we can remember, and when it has a good stock it is far from being choice about where it may grow. This is a great point in its favour, and, perhaps, one of the reasons why it grows so vigorous and plentiful in the gardens of cottages in almost every conceivable position, yielding a great many flowers during the

season. We are acquainted with a provincial town where many cottagers for miles around it and it may be so with many other towns—grow this rose, which they take to market, and few of the products of their gardens are more remunerative than their Gloire de Dijons.

All roses should not receive the same kind of management, and this rose in different positions requires different treatment. In pruning, don't slash away with the knife upon its fresh and vigorous growth without mercy ; to do so would be to defeat perhaps the *very thing* which you desire to obtain—a regular and moderate continuance of bloom for as long a period of the season as possible. We have seen this rose as a standard amongst others in a row along the sides of walks, and in this position—how differently some people manage it from others !—some persist in cutting it back in the way they generally do most other roses. This may be done at the winter pruning, but to do so during the summer season would prove disastrous. When we have come across this rose as a standard, and have had to do the best we could with it in such a position when it throws out its strong and vigorous shoots, as it is sure to do, let them *grow* to between 3 feet and 4 feet long, and then gently bend these shoots round the head of the bush, or it may be over the head, so as to form a dome. If a well-established plant, there may be shoots enough to bend both ways ; the result of doing this in place of cutting the shoots right away is generally a free breaking out from nearly every eye sooner or later, according to the maturity of shoots. These growths in general soon come into bloom—true, it makes the head look rather bulky, and sometimes causes it to be well supported to prevent wind-waving, but that is of little importance.

We recently saw a villa garden—a very pleasing way of using this round rose—there was a summer-house, the sides and roof of which were completely covered with ivy, with a plant of clematis jackmanii growing up amongst it, but concealed until it reached the top, where it was allowed to develop itself, and show off its beauty in graceful, waving growths, interlaced amongst each other, and full of flowers. There were also some plants of the Gloire de Dijon rose growing up amongst the ivy, in which its long shoots were hid, and the flowers showed well up above the ivy ; then on both sides of the entrance in this summer-house there was raised up to nearly 3 feet high against the wall, and perhaps 4 feet wide, sloping down from the ivy, a sloping bank. This, when we saw it, was in full bloom, as well as the rose and clematis. Here was a band of scarlet pelargoniums ; there the upright walls of dark green ivy ; while on the roof was a garland of flowers on a green ground. These, slightly moved by the breeze, produced quite an interesting picture.—*The Country Gentleman's Magazine.*

THE BOTANICAL GARDENS AT OOTACAMUND.

We make the following extracts from the report on the progress and condition of the Government Botanical Gardens, Ootacamund, for the year 1877-78.—

New plants.—A considerable number of new and valuable plants have been added through exchange and purchase to the garden collection during the past year ; the most important being a collection of upwards of sixty species and varieties, of New Zealand ferns. These were purchased through Captain Campbell Walker from a nurseryman in New Zealand, and with the exception of some tree ferns arrived here in excellent order, and are now established and growing well in the gardens.

A small packet of seed of the true *Cinchona calisaya var. ledgeriana* was received from Major Berkeley ; from this seed 12 plants were raised. These have been increased by cuttings to 57 ; a portion of these have been promised to Major Berkeley ; but I hope to increase the stock largely by cuttings so that a good number of plants of this valuable cinchona may be available for distribution next planting season.

In the spring of last year a gentleman resident in Wynaad sent me a small case of Liberian coffee. As he had no experience in the raising of this coffee from seed, he asked me to germinate them for him in the garden propagating houses. This I agreed to do, and succeeded in raising 410 plants, 350 of which were sent to the owner. Of the remaining 60, 30 were planted in the Burliar Garden, 17 distributed to planters in different parts of the presidency, and the remainder are now in the propagating house in the gardens.

As directed by G. O. No. 3,060, dated 2nd October 1877, four cases containing economic plants, and one case of seeds were forwarded in March last to Messrs. Nicol and Co., Bombay, for transmission to the Livingstonia Mission in Central Africa. The cases contained :—

	Plants.
Cinchona Succirubra and C. Condaminea	228
Tea, Assam Hybrid	138
Coffee Arabica	100
Orange	6
Leechee	7
Nutmeg	2
Cinamon	2
Jalap tubers	6
Ipecacuanha	12

In addition to a large parcel of cinchona and low country seeds sent by Dr. Bidie. The gardens supplied seeds of twelve varieties of Australian eucalypti and acacia, jalap, taraxicum, digitalis, cusco maize, santung cabbage, Brazil cherry and the Hill guava or gooseberry. The plants and seeds were securely packed, and it may be hoped that the greater portion of them will reach Africa in good order.

A case of Nilgiri orchids, indigenous tree and shrub seeds, was sent to A. Lascelles, Esq., Wellington, New Zealand, in exchange for araucarias and New Zealand plants and seeds.

A parcel of cuttings of rheea (*Bœhmeria nivea*) was supplied to the Madras Municipality for trial on their Sewage Farm.

Monsieur Pierre, Director of the Botanic Gardens, Saigon, visited the Ootacamund Gardens in December last, and was supplied with a complete collection of specimens of the different species and varieties of cinchona cultivated on the Nilgiris, also with a number of specimens of the indigenous shola trees.

A case of scions of the finest kinds of apples, pears and plums cultivated in Australia was imported this season for the purpose of grafting stocks in the gardens, but unfortunately they were all dead when they arrived here, having been packed in too green a state. Another attempt will be made to introduce them this season.

The catalogue of timber trees, shrubs, and flowering plants, &c., for sale at the gardens has been carefully revised and 200 copies printed. They can be had gratis on application at the garden office.

The West African coffee plants continue to grow luxuriantly, and are evidently quite at home in the climate of Burliar. The largest plant is now upwards of eight feet high, and is bearing a good crop of plump, healthy berries. Thirteen plants were raised from some seed yielded by this plant last year. From information I have received, I believe Liberian coffee has not been a success in Wynaad, except where it has been planted in warm, sheltered localities. That it will not grow, much less thrive, in the elevated districts in which the Coffee Arabica flourishes, is a point now fully settled. It requires a very much warmer climate than that variety, and in my opinion cannot be grown successfully in Southern India at an elevation over 2,500 feet. Our plants were badly attacked by leaf rust in the autumn of last year, but this disease does not seem to affect the health of this plant to the same extent as it does the common variety.

Some hundreds of young plants of *Pithecolobium saman* or rain tree has been raised from a packet of seed received from the Conservator of Forests.

The mahogany plants put out last year are making a healthy growth, the largest plants now being over 5 feet high.

Cocoa (*Theobroma cocoa*). In consequence of light crops and a succession of bad seasons in the coffee districts of Southern India, it is not suprising that planters and others are now turning their attention to the cultivation of cinchona, cocoa, and other plants that may prove an equally remunerative and less precarious investment. That cocoa will flourish in many of the coffee estates at elevations from 1,000 to 3,000 feet in Wynaad and Coorg I have not the least doubt. It might be planted with advantage between the rows of coffee bushes and in avenues along estate roads. In the spring of last year I distributed gratuitously a number of plants and seeds to planters, who find it thrive and are now anxious to obtain large supplies of plants. Already several thousand seeds have been sent to estate proprietors in Mysore, and I have registered orders for the whole crop of seed that the trees at Burliar will yield this season.

The mangosteen trees blossomed very profusely last year, and are now bearing a heavy crop of fine fruit, a small proportion of which will be reserved for seed.

AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

The Monthly Meeting of the Society was held on the 27th March, Mr. Justice Jackson presided.

GARDEN

The head Gardener's report was read as follows :—

"I am afraid there is little of interest to report this month. Labour in the various departments goes on steadily, water unfortunately taking up too much of our employés time. It we could by any means secure a connection with the canal outside, we might have a channel running through the Garden, with branches from it, to different parts of the Garden grounds, and then give our plants [which are chiefly cultivated artificially in pots] the benefit of a copious supply of water. We have secured the services of several *malees*, who will prove useful no doubt ; our every endeavour must be concentrated in securing a sufficient staff of *malees* to commence decided and active operations early these rains. Concerning Liberian coffee I must say, that the experiments which have been carried out have been exceedingly barren of results, for out of many batches of cuttings put down only three cuttings formed roots, and those were prepared with the knife in a different manner to the others, which I have tried to make plainer by the diagram sent herewith. I shall repeat this experiment. I have sent one ripe fruit of Coffea Liberica. This is just about the stage of ripeness which warrants their being plucked, they never colour highly, the fruit however will speak for itself. It is now beginning to wither up near the apex. I have also sent several others, these have grown to a certain size, and have then died. I also think the American method of striking cuttings, as mentioned by Mr. Francis of Tirhoot in last month's proceedings, is worth trying on this coffee. Seeds have been received as follows and have been duly sown :—I. Palm seeds from Botanical Garden, Mauritius. II. Moonflower, loquot, sapota, violet from Society. III. Collection of seeds from Andamans, from Mr. E. H. Man.'

"A few leaves of coleus pictus are herewith sent, as perhaps some of the Members may not have seen it thus variegated, it promises to be a very

pretty and also an easily cultivated plant. As the specimen from which these leaves were taken was grown in the shade, the colours are not so brilliant as they would be, provided they received more light, which they certainly would receive if cultivated as out-door plants during the cold season.

A report from the Garden Committee was also read. The Committee express their satisfaction at the state of the Garden and Mr. Gleeson's exertions. They recommend an order on England for a collection of ornamental plants of sorts, principally of roses, and the erection of another large house for the reception of stock plants. Agreed to.

TEA MANURE.

Messrs. Ede and Hobson, agents for Messrs. Ohlendorff's specially prepared tea fertilizer, presents one hundred weight of the manure for trial. *Resolved*, that it be distributed as judiciously as possible for trial in tea gardens, and that it be also tried in the Society's Garden.

APPLICATIONS FOR SEEDS.

Letters were read—From Baron F. Von. Mueller, applying for seed of *Reana luxurians*. As yet in two places only of Queensland have the seeds ripened, though given to many parties. The demand for the seed is very great in such an extensive country as Australia. "I will send you," adds the Baron, "more seeds of *Festuca dives*, as soon as they are ripe again; also I will try to obtain for you the seeds of *araucaria cooku*, but in the present state of trouble in New Caledonia, it may not be possible to get them readily. I am glad that the Indian Government, through the action of Sir Andrew Clarke intends to republish my "select plants." A copy with extensive additional notes will go to Calcutta by this post. The work ought to be of very great use to the whole of Upper India and ought to serve also particularly the Indian Forest Department." From C E. Feudall, Esq., Forest Department, Phillour, applying for seed of *Reana luxurians* for introduction into the Bussahir Sutlej Valley. From Col. W H. Lowther, alluding to the heavy yield of seed of *Reana*. "Fancy reana seeding so heavily in the Nepal Terai that two ounces gave fourteen pounds. Besides this there were two or three cuttings of forage. But then the irrigation resources of my friend Mr. Peppe's lands are unlimited, he has miles of water cuts." From the Deputy Commissioner, Damoh, applying for a quantity of jute seed for distribution in his district, and information as to the mode of culture and preparation. Complied with. From J. Cameron, Esq., Agra, on the subject of rhea specimens for report, and, if not approved of, test specimen to assist him in the preparation of a machine for competition for Government prize. Complied with fully.

HORTICULTURE AT KOTEGHUR.

Read the following extract of letter from Captain Pogson :—"Some years ago, you sent me a few seeds of 'New Zealand Bean,' and of my first crop I gave some to Rev. Mr. Rebsch. This bean has now become completely acclimatised here, and its seeds are called, 'Sparrows Eggs' by the Paharrees.

"In 1871, whilst at Kussowlee, you sent me two or three seeds of a magnificent pumpkin, or gourd from California, and I grew two plants, but the fruit was cut before it could ripen seed. If possible, in due time, I should very much wish to obtain a dozen or more of these seeds, and I will take care to keep all produce, but two, for seed, and let the Society have half of it for distribution to Members. "I am now located in a place having a good soil, lots of water, and a shell lime deposit, a few miles (3½ to 4) distant, consequently I can grow any thing, good land being available. I hope (D. V.) to pass five years out here, and I shall at all times be happy to grow anything, suited to the climate, which you may wish to have raised under an Indian hill sun, previous to introduction into the plains of India. I am told that a very good description of wild pea grows all about the locality, and also a large wild strawberry, the fruit being of the best description. Of course I shall put both under high cultivation and report results, sending you samples. The pea is collected, and eaten boiled, and stewed, just like the cultivated pea. It will be curious if this wild pea turns out to be the father of the cultivated kind. These remarks are equally applicable to the strawberry, with its high fragrance and large sweet fruit."

FORESTRY.

AMONGST our selections will be found a valuable memorandum by the Inspector-General of Forests on the growth of teak. The paper deals with the annual rings, girth and height at different ages, cubic contents of individual trees and the number of trees and cubic contents of growing stock per acre. Statistics have been collected from all the teak-growing districts in India. The Inspector-General invites contributions from all who have any knowledge of the growth and general characteristics of teak.

SLAUGHTERING THE PINE.—The *Oscoda News* publishes the following estimate of the cut of logs which will be attempted the present winter upon the Au Sable and Pine rivers, tributary to that place:—Estimated cut on Au Sable River, 423,250,000; estimated cut on Pine river, 32,500,000; making a grand total of 154,750,000 feet for 1878-9. During the winter of 1872-3 the cut put into the river was between 120 and 130 millions, long timber and all, and during no winter, before or since, has any thing like a similar quantity been put in. Last year the log product was 65,000,000 feet.—*Mississippi Lumberman*.

BRITISH FORESTRY.

THE necessity for the immediate institution of the British School of Forestry has been so clearly proved to be a matter of pressing importance, that it is perfectly evident to all thoughtful people that the matter cannot be delayed much longer with impunity to the national interests. Every State in Europe is far ahead of this country in everything that pertains to the *science* and *theory* of forestry, although we undoubtedly possess, man for man, the best *practical* forestry to be found in Europe or any other part of the world. If the march of improvement had been arrested fifty years ago, and things were always to remain as they then were, we might have been content to rest, in perfect ease and security, on our acknowledged superiority in *practical* forestry. In these days of scientific learning, however, mere practice without a thorough knowledge of the science of forestry is of a little real use beyond the bounds of the parish in which it is acquired, and will never raise a man above the status of an ordinary labourer, unless he is possessed of natural talents, which in a few instances may overcome all educational defects. For the teaching of the higher branches of scientific forestry in a systematic manner, no practical effort has hitherto been made, and consequently we are still without an institution of any kind, in which our foresters can be educated in the science and practice of all branches of their profession, so as to qualify them for holding the highest positions to which foresters can aspire in the British dominions. The want of the means for acquiring a technical knowledge of their profession, appears to be an insurmountable bar to the employment of our foresters in the higher grades of State forestry. No one can gainsay their claim to the possession of the highest practical skill, but her Majesty's Indian Governments, and other of our Colonial Governments require their foresters to possess a thoroughly scientific as well as a practical knowledge of their profession. With this we thoroughly agree; and, moreover, we would strongly urge the necessity of as thorough a training for our home foresters, who desire to rank above the status of common labourers. The lack of this scientific or technical training, is the only objection that can be reasonably urged against the employment of our home trained foresters in the Indian Forest Department hence the adoption by the Indian Government of the expensive, and in many points unprofitable, system of sending their forest students to study the science of forestry at the French Forest School at Nancy.

That we possess the necessary machinery for the efficient teaching of every science and branch of the art of forestry, in an equal degree to that of any Continental forest school, is an indisputable fact, that has been proved and illustrated over and over again; particularly so by Dr. J. Croumbie Brown. Almost all that is necessary for such a purpose is already in existence in connection with other educational institutions, and only requires to be energetically taken in hand and systematically arranged to produce a "Forest School" vastly superior in its teaching and training ability to anything now in existence on the Continent of Europe. In the Universities of London, Edinburgh, or the Queen's in Ireland, there are to be found all the scientific elements that are necessary for the equipment of such an institution; and that a University, or similar educational institution, is the best place for teaching the science of forestry, is now a generally accepted axiom. The system of a separate Forest School, as adopted at Nancy, in France, Munden, in Prussia, and other places, is now found to be both inconvenient and expensive, and is now being generally abandoned on the Continent in favour of forest departments, or schools, attached to established Universities. In these institutions it is found that many of the branches of instruction required in the course upon forestry, such as mathematics, chemistry, botany, natural history, climatology, engineering, drawing, surveying, &c., are already amply provided for; that better laboratories, museums, libraries, and appliances for technical education, can be maintained and be made more widely useful in the larger institutions, and that the student while following his special course, cannot fail of gaining a broader view of science by contact with what is going on around him, than he could if his horizon was bounded by the precincts of an isolated forest academy. Moreover, the students in other departments and classes of the University would give

some knowledge of forestry from what might come under their notice in that department, and the wider acquaintance thus formed would prove advantageous to all classes. A small number of special professors would be sufficient to equip any existing University for this particular service, and a large saving would be realized besides improved efficiency in the general results.

THE GROWTH OF TEAK.

THE following memorandum on this subject by the Inspector-General of Forests has been published :—

For the Manual of Indian timbers, now under preparation, it was necessary to bring together all information available regarding the rate of growth of teak, and it appears advisable to circulate the results at once with the view of eliciting further data in order to complete the account that will be given in the Manual. The following data were brought together with the assistance of Mr. A. Smythies, Assistant Conservator of Forests, Forest School Circle, North-Western Provinces.

2. A brief account of what was known regarding the rate of growth of teak up to 1873, was given on pages 357-359 of the Forest Flora of North-West and Central India. Since then, further data have been collected; but the chief addition to our information on this subject has been made by the publication of Colonel Beddome's Report of 1878 on the Nilambur teak plantations. The data here brought together in no way give a complete account of the rate and mode of growth of teak, and doubtless much more information is available which has not yet been published. It is a most important subject, which should now be taken up separately in each province where teak is cultivated on a large scale, and its study is earnestly recommended. The following remarks will most conveniently be grouped under the head of annual rings, girth and height at different ages, cubic contents of individual trees, and the number of trees and cubic contents of growing stock per acre. It will be remembered that the rate of growth of every species varies between wide limits according to climate, soil, and numerous other circumstances which affect the development of trees.

3. *Annual rings.*—It is now established beyond doubt that the concentric rings which are so marked in the wood of teak correspond each to one year's growth. The following statement exhibits the rings counted on sections of trees grown in the Nilambur plantations, which were cut in 1877. The sections were taken from the base of the stem, and with a few exceptions, the number of rings agrees with the age of the tree. The average diameter is the mean of three diameters. The statement shews the gradual increase of the heartwood as the tree grows older, and it also exhibits the number of rings on one inch of average radius in the wood of trees of different ages. But it must be borne in mind that these sections do not represent the average of each year's plantation, but were selected from the dominant trees. They therefore exhibit a more rapid rate of growth than average specimens would do :—

Year of plantation.	Number of rings counted.	Average diameter of section (wood only.)	Average diameter of heartwood.	Rings per inch of average radius.
		In inches.	In inches.	
1841	33	20·8	19·3	3·17

1871	7	7·7	4·3	1·81
1872	5	6·5	2·6	1·53
				Average 2·62 rings per inch of average radius

4. The sections ranged in age from 5 to 33 years. Dividing them into three groups, two of 10 years each, and the third of 9 years, we obtain the following as the mean diameter in inches of these three groups :—

* There is evidently a mistake here. The tree which yielded this section must have been an older tree standing in the plantation of 1852.

		Inches.
Mean diameter of trees	5—14 years old	9·72
	15—24 "	13·78
	25—33 "	18·71

A section sent from the Thingannecnoung plantation in Burma, cut from a tree 21 years old, planted in 1856, gave 21 rings on a mean diameter of 16·3", the heartwood of which occupied 14·5". This section shewed 2·57 rings per inch of average radius.

5. From other plantations also, sections of teak trees of known age were sent for the Paris Exhibition, but apparently they were not in all cases cut from the base of the stem; they are, however, instructive as shewing the rate of growth and the number of rings on one inch of mean radius.

Year of plantation.	Number of rings counted.	Average diameter of section in inches.		Rings per inch of average radius.
		Wood.	Heartwood.

1873*	6	10·1	6·	1·2

6. It will be noticed that as far as the data go, which are furnished by the sections received. Thingannecnoung and Bamunpokri exhibit an increase of diameter similar to that of Nilambur; while in the samples from North Kanara the annual rings are much narrower and the specimen from Port Blair shewed an extremely rapid rate of growth.

7. *Girth and height at different ages.*—The following measurement illustrate the rate of growth of teak in plantations in different provinces as nearly as possible from 5 to 5 years. The Nilambur plantation again furnishes the largest amount of information :—

Age.	Mean girth at breast high.	Total height of tree.
Nilambur plantation.—Alluvial soil.		
3—7 years	12 inches	29 feet.
8—12 "	17 "	68 "
13—17 "	23 "	68 "
18—22 "	25 "	71 "
23—27 "	27 "	77 "
29 "	34 "	87 "
30 "	35 "	85 "
31 "	32 "	75 "
32 "	34 "	92 "
33 "	37 "	95 "
Nilambur plantation.—Gneiss and laterite.		
7 years	13 inches.	30 feet.
16 "	14 "	50 "
20 "	21 "	50 "
24—26 "	22 "	52 "
30 "	24 "	50 "

These figures are taken from that portion of Colonel Beddome's report (paragraphs 11—44) which contains his notes on each year's plantation, and the data recorded are stated to be average figures.

8. In another part of his report (paragraph 81), however, he gives data which would seem to shew that the average size of the trees in the older plantations (all on alluvial soil) is considerably greater. He there states the dimensions of the largest, smallest and medium sized trees in four plantations, the results being as follows :—

Age.	Mean girth (probably breast high.)			Length of bole.		
	Largest.	Medium.	Smallest.	Largest.	Medium.	Smallest.
	Inches.	Inches.	Inches.	Feet.	Feet.	Feet.
30 years	67	47	29	79	65	50
31 "	69	49	30	80	65	50
32 "	63	46	30	83	67	50
33 "	68	56	43	86	68	59

The first three lines shew the average of 6 trees in each case, and the last line the average of 8 trees each. It is distinctly stated that the length is that of the bole, and not of the entire tree.

* The tree was probably older.

The plantations made on gneiss and laterite shew a much slower rate of growth than those on alluvial soil; the difference being considerable in height, and much less in girth.

9. Up to 10 years of age, the growth in length of teak on alluvial soil at Nilambur is at the rate of about 6 feet a year, and latter on it is at the rate of only about 1 foot a year. On page 358 of the Forest Flora of North-West and Central India, it is stated "that it is probable that, as a rule, teaks attains half its length with a girth of 2—3 feet." This assumption is borne out by the present figures. The trees grown upon alluvial soil in girth between 25 and 31 inches are from 77 to 87 feet high; and from all that is known regarding the growth of teak in similar localities, it is probable that, unless damaged by storms, disease, insects, or other causes, they will attain a height of 150 feet in soil of this description, and in the climate of Nilambur.

10. From Burma we have the following data. The figures from Pegu represent averages of plantation in the Rangoon, Toungoo and Tharawaddee districts, brought together on page 358 of the Forest Flora of North-West and Central India.

	Age in years.	Mean girth, breast high, in inches.	Total height of tree, in feet.
Pegu	4	5—9	15—27
	10	15	40—45
	15	23	......
Thinganneenoung ...	21	27	50—60
Garden—Moulmein ...	22	40	......

The fourth line is the average of 150 trees in the Thinganneenoung plantation in the Attaran district of Tenasserim, given in paragraph 146 of the report for 1876-77 of the Tenasserim forests. Major Seaton gives the average height at 30—40 feet, but this probably means the height to the first branch. The maximum girth was 55½ inches. The average rate of growth of the present plantations in Burma is somewhat less rapid than that of the alluvial portion of Nilambur. The last line gives the average of 15 trees measured in 1856 in a private garden at Moulmein. An instance of extremely rapid growth was the tree already mentioned, a section of which was sent from Port Blair for the Paris Exhibition, probably 6 years' old (said to have been planted in 1873, but 6 rings were counted), with a girth of 36 inches and a height of 44 feet.

11. For the Lakvalli plantation in Mysore, the following data are given in Captain Van Someren's report for 1875-76. Age 13—15 years mean girth 14 inches, height 32 feet. This is a remarkably slow rate of growth, considering that the soil is good, and the climate moist, though of course not so forcing as the climate of Nilambur.

12. The plantations in the Central Provinces and Berar have given the following:—

Plantation.	Age in years.	Mean girth, breast high, in inches.	Total height of tree, in feet.
Machna, Central Provinces ..	6	7	15—22
Pili, Berar	6	4	10
Sakata, Central Provinces ...	7	11	20—25
Pili, Berar	8	8	20
Sonawani, Central Provinces	9	12	30—40
Machna, Central Provinces ...	8—10	9	17—30

Compared with Malabar and Burma, the rate of growth is slow, as may be expected in a dry climate and near the northern limit of the tree.

13. Outside the range of the natural growth of teak, the following data, regarding its rate of growth, are available —

Plantation.	Age, in years.	Mean girth, breast high, in inches.	Total height of tree, in feet.
Bamunpokri (Sikkim.)	5	5·5	12—15
Kulsi (Assam)	5	11	29
Markúm "	4	9	18
" "	5	11	27
" "	7	16	31

The growth at that early age is fairly good; but it does not follow from these figures that teak in Assam and Sikkim will attain a great age, and produce good timber.

14. The following instances of older trees of known age in Assam and Bengal are on record:—

Locality.	Number of trees measured.	Age, in years.	Mean girth, in inches.
Gauhati, banks of the Brahmaputra...	15	87	85
Royal Botanical Gardens, Calcutta ...	19	6	16
Ditto ditto ...	8	70	79
Garden at Mohesh, Serampore ...	27	50	52

The trees at Gauhti were an average 80—50 feet high.

Trees in the Botanical Garden, Calcutta, were measured in January 1856. The older trees have since been blown down by the cyclones of 1864 and 1867.

On the banks of the Hooghly at Mohesh, below Serampore, stands a grove of teak trees planted in 1828. Their mean girth, breast high, taken by measuring 27 average-sized trees, was 52 inches. The trees were measured in January 1878, and were therefore 50 years old. They are from 40—50 feet high.

15. In paragraphs 177 and 288 of Dr. Schlich's report for 1872-73, the dimensions of a large number of teak trees at different stations of Lower Bengal are given; but unfortunately no trustworthy information regarding their age is available.

16. *Cubic contents of trees at different ages.*—In paragraph 4 of Colonel Beddome's report a statement is given exhibiting the dimensions of the trees sections of which were sent to the Paris Exhibition. As already stated, these trees were selected as samples of the dominant trees, *viz.*, of the those which will eventually be selected to remain on the ground as the ultimate crop, but, with few exceptions, they were not selected from among the largest individuals which had much outrun their neighbours. Arranging them in groups from 10 to 10 years, the following results are obtained:—

Age.	Height of tree, in feet.	Girth at base, in inches.	Length of bole, in feet.	Mean cubic contents, in cubic feet.
4—13 years	48—75	21—60	32—56	10·6
14—23 "	65—110	51—69	40—70	23·8
21—33 "	70—110	60—105	41—72	51·3

This gives us the cubic contents at different ages as follows:—

Mean age.	Cubic contents, in cubic feet.	Periodical annual increment, in cubic feet.
9	10·6	1·1 to 9 years.
19½	23·8	1·3 from 9 to 19 years.
29	51·3	2·8 from 19 to 29 years.

The annual increment increases steadily to the age of 30 years, and probably continues increasing for a considerable time beyond it.

17. *Number of trees and cubic contents of growing stock per acre.*—Regarding the number of trees and the growing stock per acre at different ages, we depend almost entirely upon Nilambur for our data. Sample areas of half an acre each were selected in each of seven plantations; each tree was measured, the cubic contents determined, and the following is the result. It is not expressly stated, but it is probable, that these sample areas were all selected on alluvial soil:—*

Name and year of plantation.	Age of plantation in years.	Number of trees, per acre.	Average length of bole, in feet.	Mean quarter girth of trees, in inches.	Cubical contents in cubic feet. Per tree.	Per acre.	Average annual increment, in cubic feet. Per tree.	Per acre.
Travelly Kava 1841	44	120	59	9·7	41	4,879	1·2	148
Elanjerry .. 1845	32	158	61	7·9	30	4,742	·9	148

Moolathamanoo 1847	30	140	62	7·5	27	3,713	·9	124
Moolathamanoo 1848	29	156	60	6·8	21	3,243	·7	112
Elanjerry .. 1858	19	270	45	5·0	8	2,208	·4	116
Wallashary .. 1868	9	750	40	3·4	3	2,491	·4	277

18. Colonel Beddome estimates that on alluvial soil, the teak at Nilambur will reach maturity at from 60 to 80 years; that fellings will be spread in each plantation over 50 years: and that the time of cutting (say at 85 years of age) the mean quarter girth will be 2 feet, the length of bole will be 70 feet, and the mean cubic contents of each tree 280 cubic feet. He also estimates that at that age, there will only be 60 trees to the acre, making the contents per acre 16·800 cubic feet.

No safe speculations can be formed regarding the future of a pure teak forest like that of Nilambur. In its natural state, teak does not grow alone, but is associated with bamboos and a variety of other trees; and it is impossible to foresee the risk of damage by storms, insects, disease, or other causes to which pure teak forests may be exposed. It may be doubted whether, even on the best alluvial soil, the average mean girth of trees 85 years of age will be as much as 8 feet. On the other hand, it is not impossible that the bole will be longer than 70 feet, and it is

* The length of stem to the top of sale measurement, were the head begins, of every tree in the plantations of 1841 to 1848, both inclusive, was measured by sending up a climber with a tape. In the plantations of 1858 and 1868 a large number of felled saplings were available, of which the average was taken.

The mean quarter girth was determined in the following manner. Ten saplings were measured breast high, and in the middle of the stem at half its length, and this gave 5/6 as the reducing factor. Those trees 30 inches in girth breast high were found to have a girth of 25 inches in the middle of the bole.

probable that it will be advantageous to allow more than 60 trees per acre. On page 155 of the Attaran Report of 1880, a plot in the Taintway forests (Yoonsaleen) is described, measuring 3,833 square feet, and stocked with 8 teak trees with clear stems to the first branch of 50 feet, the girth between 4 ft. 6 in and 6 ft. 5in.; this would give 91 trees to the acre. Full stocked forests of oak and beech in Europe 130—180 years old under favourable conditions contain 125—140 trees per acre, with a cubic contents (including tops and branches) of about 11,600 cubic feet. A forest of silver fir in the Jura, 160 years old, was found to contain 94 trees per acre, with a cubic content of 16,000 feet.

19. The total area now stocked at Nilambur is 3,436 acres, of which 1,787 are stocked with a full crop on alluvial soil, the rest not being expected to yield a full crop. In his estimate of the future value of the plantations, Colonel Beddome, only assumes 6,000 cubic feet as the full crop expected on alluvial soil.

In natural forests, where teak is associated with bamboos and other trees, the number of first and second class teak trees (above 4ft. 6in. in girth) rarely attains 10 trees per acre over large areas. The following are instances of forests exceptionally well-stocked with teak:—

Date of survey.	Forest.	Area.	Number per Acre. Class.		Total.
			Girth above 6 feet.	Girth 4½ to 6 feet.	
1870 ..	Bigram (Central Provinces) ..	50 acres ..	4	4·3	8 3
1870-71 ..	Pegu (Prome District)	17 square miles	8 6	3 0	6·6

MINERALOGY.

EVERY seam of coal indicates a fresh movement of the ground; and when it is remembered that, in the South Wales coal-field, as many as eighty distinct beds of coal may be recognized, it will be seen that the coal measures offer striking evidence of oscillations of the level of the land. Between each elevation and depression there must have been time enough for the formation of a thick vegetable soil, and in some cases this must have taken vast periods of time; thus, in South Staffordshire, there is or rather was, a famous bed of coal measuring as much as thirty feet in thickness. Remembering then the slow growth of a forest, the great thickness of some of our coal seams, and the number of separate beds in the coal measures, it will be readily conceded that these strata represent a lapse of time which is probably to be counted by hundreds of thousands of years.—*Huxley's Physiography.*—"Glasgow Herald."

THE WYNAAD GOLD FIELDS.—Mr. Brough Smith has submitted his report for the month of February. He says:—"A considerable portion of my time was occupied during the month in preparing a special report on the Alpha Mine and Works. As soon as that report was completed and forwarded to the Government, I resumed operations in the field and the survey of the following estates has been as far as practicable completed—Richmond, Elizabeth, Downham, Provident, Trevelyan, Dugley Dell, and Needle Rock. I have also examined and delineated on the maps reefs and native workings on the estates known as Sandhurst and Glenrock. Near the summit of Chic-Hudiahbetta, north of the Glenrock bungalow, there are many deep pits—for some few feet perpendicular and continued thence downwards on the underlie of the reef. These workings are traceable by deep excavations and adits quite to the base of the hill, where in a swampy spot heavy gold is said to have been found. There is a large outcrop of quartz in the midst of native workings, in the Sandhurst estate. Gold has been found in a vein not far distant from the Devalah Bazaar, and near the summit of a hill on the Elizabeth Estate; from 'leaders' which the natives have followed by making an adit about thirty feet in length, several pieces of quartz showing gold have been got under my supervision. The native workings on the north-western face of the hill are to be seen over a very large area. Indeed, the workings are nearly continuous from Richmond to Glenrock, and in another direction, from Richmond through Rosedale (where I saw a large reef with native workings), St. Thome Caroline, Adeline, and Yellamun to Yellambullay (Parcherry Hill). I have not yet been able to complete the experiments on the specimens of quartz referred to in previous reports. The planters continue to forward parcels of stone for examination, but my duties in the field have prevented me from undertaking the testing of them." The report has been forwarded to the Government of India.

WE learn from London under date the 7th March, that Mr. Oliver Pegler, Associate of the Royal School of Mines, who visited the Wynaad in 1877 and reported on the importance of the Wynaad Gold Fields to Messrs. W. Nicol and Co., and upon whose reports certain concessions were taken up, had recently penetrated into the interior of French Guiana, and found that rich gold formations existed through the country, equalling the Australian gold fields. He found bold reefs intersecting the country and rich alluvials occuring, many of the river beds giving rich yields; one small pan of dirt gave him fifteen francs worth of gold, and he has brought home many large nuggets of very pure native gold, pronounced in England to be quite equal both in largeness and purity to the earliest Australian fields. Our informant adds that Mr. Pegler states that in Guiana the soil is undisturbed and cannot, therefore, be said to be superior to Wynaad, and he thinks the reef veins in Wynaad are richer than the alluvial beds of French Guiana. We trust the Government will lose no time in publishing Mr. Brough Smyth's report on the Alpha, as we believe it deals on the past and present experience of gold in Wynaad, and, if favourable, ought to be the means of settling one of the most important questions of the day upon which the future welfare of Southern India may be said to depend, and it will be strange if, after the expressed opinions of three such eminent men as King, Pegler and Brough Smyth, the latter a gentleman of the highest reputation in his profession, some definite action is not quickly decided upon. We have more than once urged the creation of a Mining Department for Southern India, so as to regulate and fairly establish an industry which must prove beneficial to India and her people. We therefore, urge upon the local Government the desirability of losing no time in discussing the matter, if possible, before they proceed to the Hills.

The Planters' Gazette.

TEA.

THE cultivation of the tea plant in Kumaon has been fairly successful. The present out-turn is about 300,000 pounds. The Kumaon gardens used to supply large quantities of green tea to the Central Asian markets, but recently, owing to the restrictions introduced in Central Asian commercial matters by Russia, and other obstacles which have arisen, the trade has fallen off considerably. Under these circumstances, it is desirable to ascertain what other agricultural ~~pursuits the valley affords~~ scope for. It is believed that tobacco may be successfully cultivated, and also that Kumaon might supply the Indian markets with a considerable proportion of the dried fruits which are at present imported from Affghanistan. Fruit of all kinds grows there readily, and it is believed that large and well-managed orchards would prove very paying concerns.

INDIVIDUAL efforts to introduce the use of pure Indian teas in England are valuable, and should be encouraged in every possible way; but nothing short of some such comprehensive plan as that proposed by the Indian Tea Sale Co., will, we fear, sufficiently meet the want. It appears that at present there are not more than half a dozen shops in London, one or two in Glasgow, and possibly a few elsewhere, that devote themselves to the sale of pure Indian teas; and it is not difficult to understand the reason. The public taste is yet insufficiently educated; and it requires the capital of an Association; without the intervention of middlemen to sustain for a sufficiently long time retail establishments all over the kingdom for the introduction of pure Indian teas. Such an undertaking could hardly expect, at the outset, to be pecuniarily successful; but in a reasonable time profit would no doubt follow.

THE ninth half-yearly Report of the Teendarea Co. shows a profit on the season's operations of Rs. 9,464-3-10, or 7 per cent. on the capital. The outturn was 72,400 lbs., of which 63,930 lbs. sold in Calcutta at an average price of 0-10-1, and 8,470lbs. sold in London at an equivalent of 0 12-6, or a general average of 0-10-5 per lb. nett. The Report is also in other respects favourable. The Singell Co.'s half-yearly Report to December 1878, quotes a profit on the season's operations of Rs. 42,295-4-2. The total outturn was 2,58,930 lbs.; of which 26,250lbs. were sold in London at an equivalent of 0-11-11 per lb., and 232,680 at 0-9-10 per lb. It will be seen that in the case of the teas of this Co. and

the one before mentioned, the prices realised in London were palpably in advance of the rates fetched in the local market. The difficulty as regards labour is referred to pointedly in the Report. The accounts from the gardens are good, and prospects promising. The Holta Co. has not been so fortunate, and a new manager, Mr. H. Compton, has been appointed. The outturn for the season is estimated at 90,000 lbs.

The Annual Report of the Kangra Valley Tea Co. quotes a profit on the season's operations of Rs. 14,689-5-0, or over 6 per cent. on the capital." This cannot but be considered satisfactory. The average price realized for the portion of the crop of 46,240 lbs. sold was 0-13-0, and it is expected that 0-14-0 will be reached for the balance shipped to London. Mr. McDougall, a trained gardener from Edinburgh, has been brought out as manager. The estimated outturn for the forthcoming season is 56,000 lbs.

THE *Produce Market's Review* speaks of "the great increase in the consumption of Indian teas;" and yet prices continue low, and it may safely be predicated of these low prices that they will continue low so long as the tea is not made with a view to its being sold on its own merits. When it is so made, and honestly put before the public as pure and unmixed Indian tea, the prices will speedily gravitate upwards, as surely as water finds its level.

THE tea bug when it alights on the leaf, is of the ordinary grayish colour; but as it feeds, it assumes a dark greenish tint, corresponding to the sap which it has extracted, and furthermore, if it lodges on your hand or face it inflicts the same smarting and irritable sting as the ordinary mosquito. The history of the insect is of course a very interesting and essential feature in forming plans for its extinction, and we shall be thankful for any further opinions from our esteemed correspondents. We know how varied are the opinions of those who have suffered losses from this insect pest; and we should be rewarded if we could suggest any action that might mitigate the evil. That it has been most destructive there can be no doubt, and worse still it is still a growing evil, for which at present, we know of no remedy; and whoever could put planters in the way of resisting the ravages of this pest would render valuable service, especially to the tea interests of Cachar.

THE following is an estimate of the annual tea production of the world:—

China	...	...	600,000,000 lbs.
India	...	...	35,000,000 ,,
Japan	...	...	40,000,000 ,,
Java	...	...	6,000,000 ,,
			681,000,000 lbs.

IN a review of the Japan tea season 1878-9, the *Japan Herald* comments favourably upon the general results obtained. Prices opened in May well. In June and July the quality fell off. By the close of July, the export for the season amounted in round figures to 7,200,000lbs. against corresponding period 1877-8, 5,720,000lbs. The review goes on to say:

About this period the long expected black teas began to make their appearance, and their novelty attracted some of our sanguine spirits to invest, both for the London and American markets. The teas mostly offered were of inferior make and very deficient in cup quality, being poor and vapid, and sadly lacking character.

Some of the better teas were fairly handsome in leaf, being small and twisted, and some samples showed a fair amount of Pekoe tips, but the bulk of even the good grades shewed a want of finish, the leaf being imperfectly curled, and inclined to be of broken, choppy character. The water, too, of most samples, though fresh and flavory, failed to suit the tastes of the English consumers, but in this respect a more favorable verdict was received from the States.

Many of the chops of black teas came down in common native packages, and in consequence suffered no little deterioration during the time occupied in transit and detention in godowns, before the holders would submit samples for foreign buyers' inspection.

The exports during the past season were as follows:—

Export from 1st May, 1878, to 28th January.

To New York	...	...	17,771,927 lbs.
,, Chicago and Western Cities	...	...	2,863,487 ,,
,, Pacific Coast and Salt Lake, &c.	...	...	2,822,502 ,,
,, Canada	...	...	405,857 ,,
Total		...	23,683,773 lbs.

Here no mention is made of England: probably because the despatch was too limited to deserve notice, although certain parcels which reached the home market were favourably reported on, and realized fair prices. The "Heathen Chinee" is evidently, however in advance of us in India, in avoiding as far as possible, an overstocked market.

STRENUOUS efforts are again being made to raise and produce tea in America. It is found that the tea plant grows well in the States of North and South Carolina, Georgia, and other parts of similar climate. Last winter the Department of Agriculture distributed among the southern States some hundreds of thousands of tea plants, and it is confidently believed that within a few years American tea can be successfully placed upon the markets of the world, and, as it is put, "demonstrate the practicability of providing our peoples with a better article of tea than they are now able to obtain, and the possibility of saving to our country from nineteen to twenty millions of dollars in coin, which annually finds its way into the coffers of British merchants, who have substantially a monopoly of Chinese trade." A planter of Georgetown, South Carolina, has already sent up to Baltimore to be manufactured over 1,000 ounces of leaf grown on his property, which is said to have an aroma equally agreeable to the tea of Japan, or that of Moyenne in China. The latitudes in which tea is successfully cultivated in China, Assam, and Japan, correspond geographically with the latitudes embraced in the States of Delaware, Maryland, Virginia, West Virginia, North Carolina, South Carolina, Georgia, Alabama, Tennessee, Kentucky, Arkansas, Missouri, and portion of the Pacific coast, and the conditions of temperature, soil, &c., are about the same. Wilmington, in Delaware, is parallel with Peking, one of the finest tea-growing districts in China, and the upper portions of South Carolina are parallel with three of the most abundant of the tea-producing provinces. So with the other States mentioned. As a home industry, furnishing highly pleasant and profitable employment to the wives and children of certain sections of the country, it may at no distant day become an industry of great value. The possibility that the tea leaf may be cured and prepared by modern means and appliances rather than by the tedious hand processes at present employed, promises sufficiently well to induce the necessary experiments, for if successful, the expensive part of preparing would be done away with, and as an industry, tea producing be placed in comparative advance, as was cotton by the gin and sugar by the centrifugal pan.

THE CHINA TEA TRADE.

IT is generally supposed that though immense quantity of tea are consumed in Europe, the European tea-drinkers are quite ignorant of the delicate flavour that really good tea ought to possess. The finest teas are drunk only by the Mandarins, and are consequently kept in China; and the next best quality, it is said finds its way to Russia, and is consumed exclusively by the nobles, and being carried overland does not deteriorate on the journey, as tea is said to do by a sea voyage. Be this as it may—that is, whether an ordinary shipload of tea does deteriorate by a usual sea voyage from China to London—it is well known that there is a brisk competition between fast-sailing ships to bring the new season's tea to London in as short a time as possible—in short, an ocean race of clipper ships. To furnish these cargoes unusual hurry must prevail in the gathering and drying of the leaves, so that it is doubtful whether the tea so brought is after all of the superior quality attributed to it. This opinion is to some extent verified by Mr. Consul Sinclair's report on the tea trade of Foochow during the past year. He says:—"At the opening of the market in May there was manifested the same eagerness among buyers for rapid shipment by the quickest route, the same rivalry to be the first to lay

down the new teas in the London market. Evidently this is the chief aim among buyers for home consumption. One would suppose that this hurry to buy and ship off would hardly leave time for the study of the leaf; cargoes must in many instances be put on board in an imperfect state. A competition begun among the tea-men or brokers for the purchase of the teas from the country growers, and followed up by a spirited competition among foreign buyers to obtain the teas from the tea-men, cannot fail to enhance the price of the article for exportation. One other result of this double competition is, the neglect of the growers to improve the cultivation of the tea plant. The shrub is left to wear itself out; the leaf, at first left too long on the trees, in order to obtain larger eaves with greater weight of tea, is then hurriedly picked, and the tea hastily prepared. No better proof of this exists than the marked inferiority of the tea shipped from this port during the last few years.

The growers find the present production sufficient for the wants of the foreign market; it is however noticeable that from Pan-yang, Fuh-ngan, and Ping-nagn, districts near to Foochow, the quantity of tea brought to market during the past three or four years has been steadily increasing and may now be estimated at almost double what it was about six or seven years ago. In the inland districts the cultivation, or rather the production of tea, does not increase to any marked extent. Natives state the quantity of tea brought to market could be largely, almost indefinitely increased, if there existed the demand. Of late years no teas of really prime quality can be obtained in Foochow in any large quantity; the low prices on the London market and the competition with Indian-made teas has probably much to do in bringing about this result."

Unless very much care is bestowed on the picking and preparation of the leaf by the native growers, and more study devoted to the subject generally, it is to be feared that Hankow and Calcutta may eventually become the shipping ports for a safe and marketable article. Both these ports supply the home trade with fine, strong, and well-prepared teas, which are in consequence, readily saleable; they are so much liked by consumers, and are gradually gaining so from a hold in the United Kingdom that the article sent forward from Foochow is beginning to rank only as common to medium tea, and is sometimes difficult to realise.

COFFEE.

LIBERIAN COFFEE.

SINCE it was brought into commerce, this robust growing species has created a good deal of interest here. At first there were no facts upon which a right judgment could be formed, now however, the first imported plants have begun to bear fruit, and its merits or demerits may be discussed with some degree of safety.

The Liberian species forms a real tree, and I am of opinion that the dwarfer growth of the Arabian plant renders the latter a much better plant for cultivation on a large scale. The bean of the new sort is large; the beverage it furnishes is not inferior to that of the common coffee, and the productiveness of the plant seems to be a large one, the young trees having been literally loaded with berries. The most important difference however, must be looked for in the structure of fruit. The fleshy part or mesocarpium of the berry of Coffea Liberica is much more developed than it is in the berry of the common coffee plant and this is a defect which decides the matter. To comprehend this it must be considered that the tedious and toublesome preparation of the crop for the market consists exclusively in the removal of the cover which encloses the bean. The following figures, which I obtained by careful weighing, may show the great difference :—

	Weight of pericarpium and endocarpium (or shell).	Weight of ndospear (or bean.)
Coffea Liberica	4·40 grammes	1·20 grammes.
„ Arabica	1·35 „	0·60 „

The proportion of the wor'hless shell to the bean is nearly as 4 to 1 with Coffea Liberica, while it does not attain 2 to 1 in Coffea Arabica. Besides this, the Liberian fruit requires a full year for its maturity.

Resting upon these facts, I consider the new Liberian species totally unfit to rival the common Coffea Arabica as a plant for cultivation on a large scale.—*A. Lietze, Rio de Janeiro, February* 1879.

MR. JOHN PAYNE, writes as follows to the Agri-Horticultural Society from the Tinnevelly District:—"About a month after I wrote my letter of the 20th November, I was sorry to discover the finest of the two 'Liberian' plants alluded to, was attacked by leaf disease (there is not a coffee tree within miles of it). The disease appeared to have started from below, the upper portion being free. I immediately had it fumigated by having pieces of burning charcoal spread about on the ground below, and to windward, on which was cast powder of sulphur. I was afraid it was overdone, but have since learnt, further than the scorched leaves having dropped off, no damage has been done, that the plant is free of the disease, and the one within eight feet and leeward of it, is still free of any disease, so that at this moment both plants may be said to be flourishing. It will prove a palliative, but nothing more I fear, that is, one may go on fumigating for life; I am one of those that think a certain state of atmosphere has much to do with the ravages of the *Hemileia vastatrix*. I have always observed the disease to appear shortly after the blowing of a nasty cutting wind from a point, not usual at that season of the year, and whilst it lasts the disease appears to spread. The wind I speak of affects man and beast alike, going through one, so to speak, and as sure as it blows, the disease appears; yet it does not affect all parts of an estate (the poorer portion suffer first and most); some portions which to this day are free of disease; others are regularly attacked. This, I account for from the fact of the estate lying in a gully, to right and left of which are smaller gullies at various angles, so that some naturally escape the wind, and I have further noticed a continuous lay of land once attacked, the disease invariably goes through it, sometimes stopping at the ridges. I am glad to say we have less of this plague this year. A neighbouring estate was attacked most severely two years before the disease found its way into this valley, in which it first, and for two years, confined itself to the coffee plants in the forest, before coming out into the open clearings."

Mr. H. R. Dawson of Madras reports:—"In August 1877, I received from the Gardens three plants of Liberian coffee. They were about from 6 to 8 inches in height, and apparently in perfect health. I kept them in the pots in which I received them until November of the same year, when I transplanted them into the largest sized pots ordinarily used in gardens in Madras. They had then made about two pairs of new leaves each. On the 25th of March I left Madras for England, and at the same time left my plants in very good hands (Major C. C. Sargeaunt, who rented my house.) At that time two of the plants had thrown out primaries. In July, while at home, I received a letter from Major Sargeaunt, in which he mentioned that the Liberian coffee plants had suffered very much from the hot weather, and recommended their removal to my coffee estate. I returned to Madras early in November last. I found that two of the plants had made great growth, but were looking anything but healthy. The wood was bark bound, and the foliage, instead of being a dark glossy green, was a pale yellow. The third plant had been 'stumped,' and rightly so, as it was dying downwards; it had thrown up a new shoot, but I do not think that it will ever recover. The few leaves on it are yellow and partially withered. Of the two other plants, one is in a pot and one planted out in the shade; the former has recovered itself wonderfully during the past two months. It has nine pairs of primaries, and is fairly healthy in appearance, that is, it is now green instead of yellow. Its height is 3 feet, bark healthy (which it is shedding, a good feature) and no sign of blossoming, which I also take as a good sign. The plant, which is planted out, is not so vigorous as its pot companion; it has eight pairs of primaries, has somewhat recovered its colour as regards foliage, but what I consider a bad sign is, it has blossomed too early considering its age. Four blossoms expanded on the 26th January and six on the 6th instant. They appeared healthy, the blossoms dropped on the day following the expansion, the berry on the peduncle is swelling, and may with care and attention mature, but I doubt it. It is not natural for the plant to bear so early. The plant is either diseased, or the soil, which is a stiff clay, or the climate, are the causes of such precociousness. I will watch it and report results hereafter." It may be interesting to add that Dr. Cornish has succeeded in growing two healthy looking Liberian plants in a plantain tope in his garden, where they get much cool shade, and that the plants have recently blossomed.

COFFEE PRODUCTION.*

MR. TYTLER points out how that slave labor being forced is fatal to its possessors. In Brazil, it is slave labour; in Java forced labour. The great drawback, as he truly points out, is that with such countries as Brazil, the cost of maintaining labour out of crop time makes it too costly, whereas we in Ceylon obtain our labour when we require it and can pay off coolies not wanted after the crop is in, and who are only too glad to return to their country close at hand, to revisit their friends with their girdles well filled with rupees. "Where, elsewhere," he asks with great force, "do conditions of labour, such as these, suitable for coffee cultivation, exist? And a labour so suitable and so secure? It suits them, and it suits us. So long therefore as the Governments of India and Ceylon do not interfere injuriously (for interference must be injurious) with the influx and efflux of this stream of voluntary labour—so beneficial to the planter, so advantageous to the humble poor of India—so long as free currency is afforded to the natural adjustment of the supply and demand, with its own preference of route—we, as coffee planters in Ceylon, or as employers of Indian labour for coffee, tea,

* The Position and Prospects of Coffee Production as affecting the value of Ceylon coffee estates: by R. B. Tytler, of Ceylon.

cinchona, cinnamon or cacoa, or any other branches of industry, may bless ourselves that we possess a source of labour such as no other country of the world possesses for our peculiar demands. Such labour is the pivot upon which the question turns."

"The Brazilian coffee planters having in the first instance drawn off from other pursuits all the slave labour of the empire, are now on the verge of despair, seeing clearly enough what emancipation cannot fail to do for them. Mr. Tytler never believed in freed slave labour, and he saw something of that in his early experience of coffee planting in the West Indies. It is evident from the recent utterances of proprietors at their great agricultural session in the Brazilian capital, that neither do they believe in it. The author of this little work declares emphatically that they are wrecked upon the strand of labour. "Nothing in the end can save them. Endless resource of virgin forest for extension by surplus slave labour out of crop has resulted in boundless expanse of planted land, for the gathering of the crops of which there is not sufficient labour, nor can it be found. Borrowed capital, got on a superficial glossed surface of apparent, and for the time ardent prosperity, spun out a system of railways, and afforded the Brazilian the means of getting to the Barcadere his produce, to exhibit a momentarily manifest prosperity; but it was all on borrowed capital which had a basis of very questionable security, namely, slavery, and the issue of slave labour. Labour collapsing, what comes of the security upon railway debentures? What for that of the borrowed capital? What of all securities connected with the enterprise of Brazil? Let those concerned consider these questions, and, if possible, provide for them. I am merely considering how they affect the question of the supply of coffee to the market of the world, and next how this touches the value of estates in Ceylon."

It is well for Ceylon that our planters have seen and acted upon the wisdom of a thoughtful and paternal care for the comfort and well-being of their coolies. None were so careful on this point as the proprietor of Pallikellai, whose labourers were better housed and better disciplined, than the large majority of those who came to the Ceylon coffee estates. The best proof of this is to be found in the fact, that in the times of the greatest labour scarcity, Mr. Tytler never wanted for hands to cultivate his estates.

THE COFFEE INDUSTRY OF THE WORLD.

TO enable us to form anything approaching a correct estimation of labour supply as likely to affect the future production of coffee, we should not confine our observations to the new countries and those likely to come into the field as coffee producers: the whole, or if that be not possible owing to the absence of data, the larger existing countries in the field should be taken into account, and their prospects as to labor supply examined with a view to future prospects. In attempting to take but a glance at the various countries engaged in coffee production, it will be instructive if we first give the names of such colonies and countries which supplied Great Britain with coffee half a century ago, say in the year 1825, with the quantities taken from each of them. These are as follow:—

		In 1825.
Jamaica	cwts.	169,729
Demerara	,,	54,147
St. Domingo	,,	44,422
East India, Java, &c.	,,	36,735
Cuba	,,	24,057
Berbice	,,	18,558
Dominica...	,,	17,137
Brazils	,,	12 467
St. Thomas	,,	7,250
Port Rico...	,,	4,620
Caraccas	,,	3,602
St. Lucia	,,	3,353
N. America	,,	1,636
St. Lucia	,,	1,400
Trinidad	,,	1,954
Guadaloupe	,,	1,200
Bermuda	,,	792
Barbadoes	,,	236
Grenada	,,	368
St. Vincent	,,	54
Bahamas	,,	120
Coast of Africa	,,	91
Buenos Ayres	,,	64

It is instructive to note the changed position of some of the above coffee producing countries, which from fourth and fifth rate countries, have taken the lead far in advance of such countries as formerly ranked first for our coffee supplies, such for instance as Cuba, Demerara, and Berbice now sunk into insignificance. Coffee recently sold from the latter colony has been spoken of by a contemporary as though it were a new product, whereas half a century ago it was exported to England in larger quantities than coffee from Brazils.

In the list of countries producing the coffee of the present day we shall find that a great revolution has come over the coffee industry of the world, some of the old producers having altogether disappeared from the list. The following statement gives a tolerably accurate idea of the coffee imported into Great Britain forty years later than the former period:—

Ceylon	cwts.	727,038
Madras	,,	108,639
Brazils	,,	88,906
Central America	,,	63,396
British West India Islands	,,	40,312
New Granada	,,	26,623
Hayti and St. Domingo	,,	19,849
United States	,,	8,745
British India, Bombay, &c	,,	8,280
Ports on the Pacific	,,	7,962
Singapore and Eastern Staits settlements ...	,,	8,670
Philippine Island	,,	6,590
Port Rico	,,	4,378
British poss. in South Africa	,,	3,586
Egypt	,,	3,349
Other Ports	,,	3,069
Portugal	,,	1,916
West Africa	,,	1,555
British Honduras	,,	1,487
France	,,	1,268
Hamburg	,,	912
Holland	,,	627
Cuba	,,	279
Bengal and Pegu	,,	61
South Atlantic Ports	,,	20

Whatever figures may be put forward as representing the consumption of the world against the production, this much we know, that allowing for the fluctuations incidental to seasons of abundant crops and times of depression in general trade, such as that we are now passing through, the stocks of coffee throughout Europe have not seriously augmented, notwithstanding extensive plantings in Ceylon, Brazil, India, Java, and Demerara: on the contrary, present stocks are about on the average of the last five years. Reliable information from various countries shews that there is at the present moment a lull in the extension of the coffee industry of the world. Whilst this is the case, we must not forget that the populations who consume our produce are streadily on the increase, and that each year finds so many more thousands born into the world to become in due course, customers to the producers of coffee.

In Ceylon, the exhaustion of our forest land, in Brazil the labour difficulty, and in many countries coffee pests and other impediments stand like lions in the path of progress. It is worthy of note that whilst we in Ceylon have been inundated with labourers of all descriptions, many worthless, it is true, by the recent famine in South India, the terrible year of drought and starvation in the Northern provinces of Brazil does not appear to have added a single, labourer to the coffee plantations of the South, a sure evidence that they have nothing to hope for, nothing to calculate upon in the indigenous labour of the empire. At the very time when tens of thousands of pounds were being voted by the Brazilian Legislature for the famishing inhabitants of the North, the planters of the South were discussing and lamenting, in full assembly, the starvation of their labour supply and the gloomy outlook before them in consequence. Nor has the great coffee country of the South American Continent escaped the ordinary trials which beset the industry elsewhere. There, too, they are suffering from unfavourable seasons and from a pest which promises to become serious in the future, if not so detrimental as leaf disease.

What has been the influence thus far of railway construction and higher cultivation in that extensive country, may be judged from the latest statistics of the Brazil coffee trade, which give the following as the exports for three years ending December 31, 1878:—

		1878.	1877.	1876.
Rio	tons	16,7240	162,105	159,043
Santos	,,	64,762	40,795	38,929
	Tons	23,202	202,900	197,972

How much land may have been brought under coffee cultivation during the last few years of high prices is not known, but it is not likely that this will continue in view of the extreme difficulty of supplying the necessary amount of labor for existing cultivation. Whatever quantity grown, will, with the present and other lines of railway in course of construction, be brought more rapidly to market, but it is improbable that railways will help the labor supply, for the mule drivers and others now engaged in the old fashioned mode of transport, when thrown out of work by railways, will not take to labor on estates.

TOBACCO.

TWO years ago Messrs. Begg, Sutherland and Co. took over the Ghazipore tobacco-farm which had hitherto not been very successful. Under their care, however, very favourable results have been obtained, and it may be fairly hoped that the cultivation will continue to improve and extend. The results would have been still more satisfactory, but for the continuous ill-health of the curer, Mr. Williamson. Some tobacco sent home for sale last year realised three times as much as any Indian tobacco previously exported. An English firm of tobacco manufacturers have offered to take a large supply of the leaf annually at rates which will give a fair profit. A trained cigar manufacturer is shortly to be added to the assistants on the farm, and it is hoped that Messrs. Begg, Sutherland and Co. will soon be able to supply a good brand of cigars. An attempt made last year to grow tobacco at Kumaon did not prove very successful, but another endeavour is to be made this year, and it is hoped the results will be more satisfactory.

INDIAN TOBACCO.

BELIEVING you take considerable interest in the cultivation of the tobacco crop in India I beg to say I have been nearly twenty-five years engaged in growing and manufacturing tobacco in South and North America, and during the past three years I have taken considerable interest in the weed grown in India. During the past month I have been in the tobacco-growing districts of Madura, the Pulney Hills, Trichinopoly, and along the line of the South Indian railroad. In every place I visited I found splendid specimens of the leaf tobacco, which if properly cured would compare most favourably with the very best grown American leaf tobacco, and from which I have no hesitation in saying can be produced or duplicated the most celebrated brands of American cake or plug tobacco, as well as the famous brands of smoking tobacco, *viz.*, "The Lone Jack," the "Fruits and Flowers" of old Virginia, the "Golden Sceptre" &c., all of which cost an enormous price in Madras. This could be done, if the tobacco was properly cured, but it is not. How can we have it cured as it should be? By teaching the cultivators the method used by the planters in America, Spain, and Cuba. You may ask me, "How are we to teach the proper method of curing tobacco to our planters?" I will tell you, Sir, by printing a small book and having it widely distributed through the Madras Presidency, as I believe Mr. Buck has done in the North-West Provinces, advocating the best methods of planting and curing tobacco. Mr. Buck deserves all praise for his efforts to improve the cultivation of tobacco, although he admits he has had no practical knowledge, and has compiled his book from information given him by others. Another advantage will arise from the proper cultivation and curing of tobacco. You can ship tobacco to England, and successfully compete with the American shippers who receive very high prices for their produce. Three years ago I saw 1s. 2*d.* per lb., paid in the Liverpool Market for fair "Virginia" sun-cured tobacco, and I am quite sure you have, or could have, produced in this Presidency quite as good. Again, you have a great advantage over the American planter. He has, in many instances, to cure his tobacco by fire, which injures and gives the leaf a very bitter taste, whilst your planters can at all times sun-cure their tobacco. Your planters do not know it perhaps, but they can raise and cure two crops yearly in this Presidency. I saw the experiment successfully tried in the Coimbatore district last year. On the whole, I believe, the tobacco grown in India is better than that of America, for you can make cigars from nearly all grown here, whilst in America but one or two sorts are capable of producing tobacco fit for cigar-fillers, and the wrapper must be imported from Spain or Cuba. Connecticut, Massachusetts and Delaware produce a small quantity of cigar-tobacco yearly; Maryland, Virginia and North Carolina are justly celebrated, and manufacture nearly all the fine brands of Plug and smoking tobacco exported. The tobacco grown in the Western States of Tennessee, Ohio, Kentucky, and Missouri is very coarse and strong, and can only be used for Navy Plug. Your planters can do all that those States I have mentioned can do. But with all your advantages, you will rarely find as good a cigar here as you can purchase in either England or America; and the reason is, your cigar merchants do not prepare the tobacco to be used for cigars properly, nor do they pay the proper attention they should to the cigars when made. Thus you will often find a cigar that will not smoke, and again if it does smoke, it will often make an unpleasant noise, somewhat like that of a dirty or wet pipe. I will not trouble you further at present on the tobacco question, but should you desire it, I will give you the best methods adopted in America and Cuba—1st for preparing the seed beds, cultivating, manuring &c.; 2nd cultivating and manuring the ground for the plants, as well as the care required to bring the plant to maturity; 3rd, curing of the same; 4th, the proper way the tobacco should be handled and packed for exportation to England, &c.; and lastly, the manner of preparing and curing tobacco for cigar making—and when made, the manner in which cigars should be cured and packed.—*Tanjore Correspondent.*

CINCHONA.

CINCHONA CULTURE.

WE are glad to see that Dr. Biddie has published in the form of a handy little pamphlet of 24 pages duodecimo, his interesting and useful lecture delivered at the Madras museum on this subject. The brochure is entitled "Cinchona culture in British India, being a brief sketch of its origin, with practical hints on the chief points connected with the industry by G. Bidie, M.B. Madras, Higginbotham and Co., 1879." Coming from such a pen, the practical hints, which are the valuable part of the book, are sure to be reliable, for besides other means of being well informed on the subject, it is mentioned in the preface that it was Dr. Bidie's "good fortune, as well as pleasure, to have visited the Government cinchona estates very frequently, and to have enjoyed special facilities for gaining information during those visits." It will be remembered that Dr. Bidie was selected to be one of the late Government commission on important questions in connection with the best manner of utilizing the cinchona bark. Perhaps, the best way of giving our readers an idea of the nature of this very business-like little production, is to present them with a copy of the table of contents, which runs as follows:—"Introduction—Introduction of the cinchonas into India—Government action in cinchona culture—Botanical sketch of the cinchonas—Remarks on the habitats of the cinchonas—Chemistry of cinchona barks—Discovery of quinine—Medical value of the several alkaloids—Local manufacture of a cheap cinchona febrifuge—Proportion of alkaloids on the several barks—*Red Bark—Crown Bark—Yellow Bark*—Other species—Hybrids—Changes in cinchona bark according to the age of the tree—Culture of cinchona—Manuring cinchonas—Harvesting the bark—*Mossing, coppicing, uprooting*—Comparative yield of bark by the several systems of harvesting—Drying the bark—Seasons of the year at which the barks are richest in alkaloids—Cinchona culture likely to continue remunerative?" There are two plates and two diagrams in the pamphlet, the price of which is fixed at one rupee.

SERICULTURE.

SERICULTURE IN INDIA.

IN reference to our incidental remark a fortnight ago on sericulture in Dharwar, as it used to be carried on a few years ago, a correspondent sends us the following:—

"The great advantages of Dharwar, over other places in Western India are:—1st an admirable medium climate all the year round; 2nd, a medium rain fall—so that the atmosphere is never too damp or very hot; 3rd, mulberry shrubs grow admirably and never fail; and 4th, you have the monthly silk-worm which thrives well, throws off cocoons eight or nine months in the year, thus giving steady work to the people engaged. 5th, the silk is easily wound off and even though roughly reeled by the hand, produces such beautiful dresses as you have seen. If these advantages are not sufficient, I do not know where you get any thing like them in India. I think to these above points I might add a caution, viz., that when they find the monthly worm doing well, don't breed it with any other, but be content; this indiscriminate crossing has caused the continual failures in sericulture in Southern India."

SILK OF THE TASAR WORM.

THE following Government resolution on this subject has been issued:— In the Resolution of the 23rd November 1875, the Government of India stated the facts regarding the production of tasar silk so far as they were known to it, as well as the steps taken or under consideration in reference to the utilisation of this article and the development of a regular industry. The general conclusion which seemed to be justified by the information before it was, that the domestication of the tasar worm offered no prospect of remuneration even if the process were in itself possible; but that if certain difficulties arising from natural conditions connected with the collection of the worm in its wild or in a semi-domesticated state could be overcome, and that if the silk could be satisfactorily reeled and dyed,—for difficulties had been encountered in connection with both processes,—a regular and extensive export trade from India to Europe, either in the shape of cocoons or as raw silk, would spring up; for it seemed certain that European manufacturers would take the raw produce if laid down at reasonable prices.

2. The first step to be taken, however, was to procure further information. It was obviously premature to take any measures having in view the creation of a regular industry without first obtaining definite information on important points on which information was wanting either wholly or in part. Such points were; the exact cost at which the raw material could be collected or produced in commercial quantities, both in the wild and semi-domesticated state; the cost of reeling the silk; the weight of silk in proportion to cocoon; the degree in which the filaments would bear *croissure*; and the consequent ultimate value of the silk in the market. As a first step towards the obtainment of such data, the Government of Bombay and the Chief Commissioner of the Central Provinces were requested to collect a quantity of cocoons in order that careful experiments might be made with them in this country, as also under the direction of her Majesty's Secretary of State in some of the leading filatures in France and Italy. This was done, and the results of the experiments undertaken by Mr. Wardle under the direction of the Secretary of State with the cocoons thus supplied are now before the Government of India and are stated in his reports attached to this Resolution. No experiments were made in this country, the gentlemen to whom cocoons were supplied for the purpose having pronounced them to be old and unfit for reeling, especially in this country, where the special machinery and appliances required for this purpose are not available. This is of little consequence, however, considering the success of the experiments in Europe, and having regard to the fact that in all probability filatures in India for tasar silk will not be required, and that only a trade in cocoons will prove remunerative.

3. At the same time that these cocoons were collected in the Central Provinces, the other local Governments and Administrations were invited to make proposals and suggestions in the matter.

4. The result of the enquiries and experiments made in India has not, on the whole, advanced matters very far. In the Bombay Presidency the experiments undertaken by Major Coussmaker for the semi-domestication of the worm were interrupted by the drought and famine. They have since been renewed but as yet with inconclusive results. These are stated in a letter from Major Coussmaker, from which the following paragraphs are extracted:—

* * * * * * * *

"2. My former experiments, as well as those conducted by Mr. Woodrow, had proved that it was a mistake to attempt to rear these worms on twigs either those cut from road-side trees, or from those which had received some care and attention in a garden, and that the plan most likely to succeed was to feed them on shrubs in localities where they could be protected from their enemies, and, if need be, from unfavourable weather. With this view, I began to collect young plants.

"3. I had noticed in 1876 that the tasar worm throve well on *Lagerstræmia indica*, an ornamental shrub, fairly abundant in the cantonment of Poona; this is a plant which throws up a good many suckers during the monsoon, and I soon got a few plants together. I took a house which was well supplied with shade and water, and my gardener managed to collect 172 plants between December and July, many of them only a few inches high, but some were large enough to be of use. There were also in the ground six bushes, and my first care, when I came in from the districts, was to cut them all back to the hard wood, and apply to their roots a fair amount of manure. The consequence was that as soon as the rain commenced the plants shot most freely into leaf.

"4. Mr. Woodrow had not been able to save any seed cocoons, but I had found three female cocoons in the districts, and the Marathi woman, who had been my chief assistant in looking after these worms before, had collected twelve. I soon had several moths from these cocoons, and found, as I had noticed before, that there was [illegible] difficulty in getting an abundant supply of fertile eggs. Hardly any [illegible] were wasted; it was only necessary to put them out over-night, on any bush, and it was almost a certainty to find them paired at daybreak. I found that it was not necessary to tether them; they rarely moved from the twig on which I placed them. As fast as the young worms hatched out, I put the trays containing them among the leaves of the [illegible] and in a few [illegible] they commenced [illegible]. The weather was every[illegible] I could desire, showery with [illegible] of fine weather; the bushes were full of young [illegible] worms thereon as I have never seen them [illegible] before. I tied bamboo screens together and covered over the plants as they stood in the open. The worms changed their skins at intervals of 4 to 5 days instead of 5 to 8, as had been the case when I reared them indoors on gathered food, and they spun their cocoons in 28 to 35 days instead of 40 to 50, as I had noted before. The moths came out of these cocoons in 27 to 30 days, and their eggs proved fertile, producing caterpillars which grew as fast and as large as the first. The only difference that I observed was that the 'cement' of the cocoons of the later crops was less uniformly white; this may have been due to the changes in the weather or the quality of the leaf, some shrubs having been eaten off three and four times this monsoon.

"5. The *Lagerstræmia* bush proved an excellent food; it flushed so quickly that a plant 2 feet high, after being fed off quite bare, cut back and re-potted, was again in thick leaf in a fortnight, and the same batch of worms stripped it again. In changing the plants, and in daily examining the cages, a few accidents occurred; but 100 worms yielded 71 cocoons.

"6. I enclosed an old *Carissa carandas*, which had neither been pruned nor manured, with bamboo screens, and liberated 50 worms there. In the course of a month I gathered 31 cocoons, a little larger than those of the *Lagerstræmia*, but much harder and yellower. The caterpillars seemed to thrive a little better on this bush, and completely stripped it, but the tree did not recover quickly, and did not yield another supply of food the whole monsoon.

"7. I put six worms on to a young *Zizyphus jujuba* tree in my garden, but neither enclosed it, pruned it, nor manured it. It had a great deal of leaf and flower on it, and the worms ate both. They grew very large and healthy, being in every stage of their existence a little ahead of some of the same batch feeding on *Lagerstræmia*. Five cocoons were spun here, larger than any that I had gathered from off the other trees.

"8. I let the majority of the moths fly away, for as soon as the male has left her, the female is quite ready to go and look for suitable trees to deposit her eggs on. I had not enough food for more than 100 worms at a time in my own compound, and almost every attempt which I made at bringing them up elsewhere, unsheltered by the screens, failed. Crows, squirrels, and other enemies carried them off, and I hardly got a single cocoon; but in my own compound I continued to rear a few at a time, changing them from one tree to another as I found it expedient. The result of the experiments which I made showed me plainly that plants in the ground, with or without screens over them, gave the most suitable food; that it mattered not whether the young shoots were eaten down by the caterpillars or cut off by the pruning shears. The *Lagerstræmia* never sprouted again, and it was only the very limited supply of food which I had that prevented me rearing many more worms.

"9. From the single experiment I have mentioned, *Carissa* does not seem to recover quickly. *Zizyphus* seems to grow very fast, principally at the extremities of its long straggling branches; but as I only had one tree in my compound, I could not be sure about its usual habit of growth.

"10. I baked some of the cocoons gathered from each of these three trees and sent them home to Mr. Wardle, asking him to give me an opinion on the qualities of the respective fibres. I had all the burst and injured cocoons cleaned, and sent them, together with those which Mr. Woodrow had on hand, to the Alliance Mills in Bombay to be converted into yarn. I have kept some fifty seed cocoons for next year's experiments.

"11. I have got together a good many plants for next season's experiments—353 *Lagerstræmia indica*, 10 *Lagerstræmia parviflora*, 18 *Conocarpus latifolia*; plants and cuttings all rooted and in leaf; also 136 *Carissa carandas*, 135 *Zizyphus jujuba*, 105 *Pentaptera tomentosa*, seedlings. There are besides 8 *Zizyphus* bushes in the compound, and if my gardener will but take care of these during my eight months' absence from Poona I hope to resume my experiments under better auspices.

"12. The past season has been very favourable for tasar worms. Mr. Lyle, who was cultivating them to a small extent at Dapuri in 1876, tells me that some of the men who were under him then came to him lately and asked him whether he wanted any more cocoons as they had seen several. He happened to be on the spot and sent a man to see how many he could collect within three hours. He came back with 800, and said that he had heard that some people had been taking them into Poona for sale, presumably to the native physicians. I myself have already found many more casually this year in the districts than I usually do."

* * * * * * * *

5. In Madras, in the North-Western Provinces and Oudh, in Burma, and in the Hyderabad Assigned Districts, as also in Mysore, there would seem at present to be no prospect of establishing any traffic in the cocoons or raw silk of the undomesticated worm.

6. The late Chief Commissioner of Assam thought that any attempt to foster the trade in Sylhet would prove unsuccessful, and refrained from offering any suggestions beyond drawing attention to the existing and old-established silk industries of Assam, which in his opinion might have opened up a wide field for private enterprise were it not for the extraordinary delays that exist in communications between the province and the rest of India. Government have under consideration the question of improving the facilities for communicating with Upper Assam. It is hoped that when the contemplated improvement is effected, Colonel Keatinge's expectations will to some extent be realised; for there is at least as great a demand in the European markets for the cocoon of the eria and moonga worm as there is for that of the tasar.

7. In Bengal the tasar worm appears to abound in various localities generally in all the tree and scrub jungle lying south and west of a line marking the southern and western limit of the continuous cultivation of the Gangetic alluvial and of the Orissa littoral. Whether the insect is of one or of several species, is a matter of doubt, and the season and mode of breeding and collecting appear to vary with the locality where it is found. The price of cocoons, it is alleged, ranges from Rs. 6 to Rs. 16 per kahan (1 kahan=16 pans of 80 cocoons each, i.e. 1,280 cocoons); and in regard to its yield, one kahan makes in Bancoorah two pairs of dhotees, in Sooree 15 chittacks of silk, and in the Sonthal Pergunnahs from 1½ to 2 seers. These and other more detailed particulars, furnished by the Government of Bengal though admittedly incomplete and unauthenticated in some respects, are useful as far as they go, and the Government of India will be glad to be informed of the measures which are being taken to gather further particulars, as well as of their results. The Lieutenant-Governor's opinion on the proposal made by Mr. J. Deveria, to the effect that the State should undertake the rearing of tasar cocoons in the jungle mahals of Chota Nagpore for sale to reelers and exporters is also awaited.

8. From the Punjab, some samples of tasar silk, reeled from cocoons produced in the Hoshiarpur district by the Deputy Commissioner, were reported on by the authorities whom the Government of India consulted as fairly successful. Some specimens of cloth, which were also received from Hoshiarpur, were found to have been very creditably manufactured.

9. The Secretary of State, in acknowledging in his despatch No. 25, dated the 22nd March 1877, the receipt of the cocoons gathered in the Central Provinces, has forwarded a report by Mr. T. Wardle, from which it appears that although the cocoons, when made over to the filatures in France and Italy, were found to be very old and imperfect, the reelers spoke most hopefully of the results that might be attained with fresher cocoons properly gathered and prepared. Mr. Wardle, too, said that he was prepared to dye tasar silk as reeled in Europe by his improved processes in almost any colour, even to very pale shades.

10. The first part of a further report from Mr. Wardle has meanwhile been received under cover of the Secretary of State's despatch No. 61, dated the 29th August 1878; as also some samples of tasar silk displayed at the Paris Exhibition, as prepared under Mr. Wardle's instructions. These specimens, which can be seen at the office of this Department by persons interested in the matter, are far superior to anything ever yet seen of the same kind, the organzine especially being remarkable for its excellence. The grége is softer, cleaner, and altogether better than the best raw tasar silk as yet reeled. It is clear from these samples that such difficulties as existed in the reeling of this silk have been completely overcome. Mr. Wardle's process produces silk so fine as to be capable of adaptation to any purpose for which mulberry silk is used. Excellent results have also been obtained in the spinning of tasar thread and the weaving of fabrics from spun silk. Mr. Wardle's experiments with the dyeing of the silk have also been quite successful. On the whole it is certain now that there is no inherent obstacle to the utilisation of this silk for manufacturing purposes.

11. The main question now to be answered is that of cost. Whether silk of this kind will be extensively consumed, depends upon the price at which it can be placed in the market. Mr. Wardle states that the cost of making organzine and tram from the cocoons is 20 francs the kilogramme, viz., 10 francs for reeling and 10 francs for throwing. This is double the price at which ordinary tasars are now sold, and it is not easy to say whether purchasers will be found for the improved product greatly superior as it is, though it seems that the price is susceptible of reduction. As yet the only indication of the prices likely to be given for tasar silk is an offer made by M. David, a silk manufacturer of St. Etienne, who expresses his readiness to take one or two thousand kilogrammes of cocoons delivered at Marseilles at the price of one franc the kilogramme. This price, it is clear, is much too low, for, according to the information before the Government, cocoons could not probably be laid down in Europe at less than three or four times the sum mentioned. This, however, is a matter which admits of local verification, and it should form the subject of enquiry.

12. The results obtained by Mr. Wardle, as well as by others working independently, are so important and so full of promise as regards the manufacture of this silk and the utilisation of the manufacture for apparel and other purposes, that it is eminently desirable to thoroughly investigate the question of production. Information on this subject has been sought from various quarters, but information in the possession of Government is not sufficient to enable it to furnish precise answers, yet it is necessary, if the attention of capitalists is to be attracted to the development of this industry, that full information should be forthcoming. M. Natalis Rondot, a delegate from the Chamber of Commerce of Lyons to the Paris Exhibition, and President of the Jury in the Silk Section, has written to the Government of India, asking for information on the following points, not only as regards the tasar worm but also as regards other undomesticated worms:—

(1) an enumeration of the different kinds of wild worms;
(2) the districts from which each kind is obtained, and in what quantities;
(3) the species of worm from which each kind of silk is manufactured;
(4) the trees on which the worms feed;
(5) the uses to which the silk is put by the natives;
(6) the markets where they are to be purchased;
(7) the probable prices of dry cocoons of each kind and of the silk as reeled by the natives;
(8) the probable quantities retained for local consumption and available for exportation to European silk mills;
(9) and the outturn in money value of the silks woven in India, which Rondot thinks must be considerable, especially if tasar and other similar silks commonly worn by the natives are taken into account.

13. M. David, of St. Etienne, also asks for information on the following points:—
(1) the nature of the chemical agent used by natives to soften the cocoon;
(2) whether the natives can reel a cocoon more than a year old;
(3) the length of time elapsing from the spinning of the cocoon and the emergence of the moth;
(4) whether the dark and light coloured cocoons which are found mixed in the bales sent from India are of different varieties, and whether they are found in the same localities;
(5) also, whether it would be possible to obtain bales containing only light coloured cocoons.

14. Some information but of a vague and general kind, exists on a good many of the points enumerated by M. Rondot, and the Governor-General in Council desires that an effort may be made to cause such specific information as is obtainable, with special reference to the quantity obtainable, and the prices on the spot, to be furnished with as little delay as possible. It is also much to be desired that particulars of manufacture should be obtained as far as possible.

The particulars of the outturn of the filatures in Bengal are unknown; for, though the quantities exported and their values are ascertainable, Government is unable to say how much of the outturn of the filatures (there are a great many native filatures) is kept in the country, or what it is worth. Of the small local native reeling (small separately, but large in the aggregate), no more is known than of the handloom village weaving of cotton. In Assam and Burma, silk reeling and weaving are a domestic occupation of the women of the house; in other provinces it is a trade. In Bombay, there are two mills worked by steam in which silk is woven, but the extent of their operations is unknown. In short, no precise statistical account of the silk industry in India is extant, though there is a good deal of information of a more or less vague and general character. As regards silk production, Mr. Geoghegan's account of silk in India contains practically all the information that Government possesses, although for some years past much attention has been paid to the production of tasar silk. The same is to be said of the other kinds of wild silk. These are all separately distinguished and shown in Mr. Geoghegan's book, in the section given to the wild silk producers, as well as in the appendix by Captain Hutton. Interesting information, though in most cases of a general character, has been furnished by the local Governments and Administrations, but more precise information is now desirable, and the Government of India will be glad if the Government of Bengal and the Chief Commissioners of the Central Provinces and Assam will take measures to collect it, and furnish a report giving a categorical reply to the enquiries of both M. Rondot and M. David.

INDIAN AGRICULTURIST.

A MONTHLY

JOURNAL OF INDIAN AGRICULTURE, MINERALOGY, AND STATISTICS.

VOL. IV. CALCUTTA : MONDAY, 2ND JUNE, 1879. No. 6.

NOTICE.

The INDIAN AGRICULTURIST *will be supplied to all Schools and Missionaries in India at half price.*

R. KNIGHT.

Calcutta, 1st Feb. 1876.

CONTENTS:

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.

CORRESPONDENCE.

SWAMP CULTIVATION.

TO THE EDITOR.

SIR,—I wonder if the scientific agriculturists who bewail the degraded state of agriculture in this country and speak so contemptuously of "swamp cultivation" have ever realised the fact that the best rice land in Tinnevelly (and I dare say elsewhere) produces *every year* without fail 3,654lbs. of clean rice; and not only shows no tendency to deteriorate but often produces a crop of pulse in addition. To enable any one to check my figures I will give the details of the calculation. 40 *kottais* (a local measure containing 168 *pucka* seers) is not an unusual crop for a *kottai* of the best double crop land. A *kottai* of land is equivalent to 1·62 acres: so that an acre would produce 24 11/16 *kottais* of *paddy*. It is considered here that 21 measures of paddy will give 9 measures of cleaned rice *after paying all charges of cleaning*. At that rate 168 *pucka* seers of paddy would yield (3×24=) 72 *pucka* seers of *rice* or about 148lbs., this multiplied by 24 11/16 gives the number of lbs. per acre as shewn above. Expressed in imperial bushels (of 60 lbs.) the yield would be 61¾, and it must be remembered that this is practically a *never failing* crop, and that very often a crop of pulse is reaped between the two crops of rice.

I may add that an ordinary rent per acre for the best land is 13 *kottais* of paddy, which at present prices is worth Rs. 104 to 130, or 4 to 6 times the assessment including all cesses.

TAMBRAPARNI.

THE SAGO PALM.

(*To the Editor of the "Straits Times."*)

SIR,—A great deal of attention has been drawn to the East lately on account of the high price of land in Ceylon and India. Cheap land can be got in Sarawak in any quantity, and land too particularly suited to the culture of both tea and coffee, but I wish to point out to your readers a new culture which is doubtless far more profitable than either, that is sago.

The sago palm grows to perfection in Borneo. At present the planting is entirely in the hands of natives and the manufacture in the hands of Chinese. To give to your readers some idea of the extent of this culture in Sarawak, I may mention that our trade returns for last year shew an export of six thousand six hundred and ninety-five tons of manufactured sago, value four hundred and nineteen thousand, nine hundred and fifty-nine dollars.

I shall now give estimates for a plantation on a comparatively small scale, and as I have given the matter careful study the figures and facts given may be relied upon.

Estimate for a sago plantation of 500 acres.

To price of 500 acres of land	$ 500
Felling and clearing @ $4 an acre ...	2,000
Planting @ $1 per 100	250
Carriage do	950
26,000 pieces of Billian fencing	780
Putting up do @ 5 cents per fathom ...	160
Coolie house, tools, &c.	100
	$4,040
Interest on do 10 years @ 10 per cent ...	4,040
Mandore and 10 men say $60 per mensem	7,200
Interest on do	3,600
	$18,880

The best distance to put in the plants is about 30 feet apart; 500 acres would therefore carry about 25,000 trees. At the end of ten years

there would be, say 15,000 trees fit to cut; natives are in the habit of working up trees at half profits, and as each tree will yield an average of 5 pasus or 2 pikuls of raw sago, always worth in Sarawak $1, the profit the first year would exceed the whole outlay, and the plantation should continue to yield a profit of from $ 15 to $20,000, or about three thousand pounds sterling yearly. As it might be difficult to get natives to work up such a quantity, the better plan would be to erect machinery for pulverising the trees and for the manufacture of sago flour for either the Singapore or European market, when the profits would be considerably larger.

I fear my figures will shew such a profit that your readers will say: "If it is such a good thing how is it Europeans have not taken it up?" I can only conclude that partly want of knowledge of the profits, partly the long time that must elapse before any returns may be expected, and partly the fear of depredations of the wild pigs may have deterred them. It will be seen in my estimates that a Bilian or Iron wood pagar is a considerable item. I make this a *sine qua non.* If this fence be so closely and strongly made as to keep out the pigs, there is no fear of the success of the scheme as the palm will require little or no looking after.

In some ground the sago tree comes to maturity in 8 years, and as each parent tree is surrounded with young ones which ripen in due succession, a sago plantation once made will never be exhausted. I may mention that Bilian wood is impervious to the attack of either white ants or rat, and will last 200 years. In this culture there is no fear of either long draughts, heavy rains, or violent storms damaging your plantation as in tea and coffee. The only drawback is that the best sago lands are found in low lying swampy ground which makes working the plantation anything but a pleasant occupation. Such lands are in fact scarcely fit for any other culture, and we have no doubt the Sarawak Government would gladly make free grants for such a purpose.

The larger the plantation the greater the proportion of profits.

I am, &c.,
W. M. COOCKER,
Resident of Sarawak Proper.

THE PRICKLY COMFREY.

(*To the Editor of the " Times of India."*)

SIR,—Having noticed letters in your paper regarding the "prickly comfrey," I should feel obliged by your inserting this letter also, which I trust in time may be answered, giving me the information I seek about the plant as a forage for horses. The circumstance which has prompted me to write is as follows:—

A short time ago, in this station, a tonga pony had been daily getting a bundle of "prickly comfrey," and being the only animal in the stable that relished it, got the whole bundle, which in size was about as much as one could grasp in both hands; but it evidently did not agree with the pony, as it brought on indigestion, which ended in sleepy staggers, and he died on the fourth day after the staggers came on, having been in a perfect state of coma for some ten hours previous to death. The symptoms in the case were so very marked that there could be no mistake as to the ailment; and the treatment was carefully carried out. I should mention that the pony was a Deccanee, hardy and strong in constitution, and had done regular tonga work for some time past. The owner could ascribe no cause for the pony's illness other than the "prickly comfrey," and as I had the case under treatment, I feel sure that the cause assigned is the correct one. I am well aware that forage to which the stomach is unaccustomed (although wholesome of its kind) will produce indigestion in the horse; yet I cannot think that the bundle the pony got daily was too much, if the plant is a wholesome forage. I should very much like to know if the "comfrey" is considered a wholesome forage for horses, and if so, how much of it can be safely given? Is it necessary to dry the leaves a little in the sun before giving them to a horse, or to prepare them in any way? And, also, at what stage of the plant's growth should it be cut for forage?

B. G.

Hingolee, 8th May, 1879.

BAMBOO CULTIVATION.

(*To the Editor of the " Englishman."*)

SIR,—Referring to Dr. King's letter in your journal of the 6th February, as I understand the question at issue between him and myself, it is as follows.

In February 1876 experimental plantations were ordered to be established by the Government of India for the purpose of testing the cultivation and cropping of bamboo, and in a "memorandum" then officially issued by Dr. Brandis the Inspector-General of Forests, he directed attention to the main points to be determined thereby; among other suggestions in this "memorandum" Dr. Brandis clearly pointed out "that the experiments undertaken *should be as much as possible comparative*; of a number of clumps of the same age, and species, and growing under the same conditions, *some should be thinned lightly, others heavily, and the third group should be cut completely, leaving only a few old stems on the ground.*"

Now what was the course pursued by Dr. King?

Did he adopt *any one,* of these *three,* most practical and common sense suggestions?

By no means:—but on the contrary he confined his experiments to "*one single faulty system*" which he terms "Utopian" *i.e.*, chimerical, adding, "nobody can have a poorer opinion of the merits of the system which was followed in this experiment than I myself have."

To justify his failure (which I very naturally I think criticised) he now wishes to "*father*" this system on me, and to substantiate this quotes *ingeniously*, but not *ingenuously*, from my pamphlet:—I say *ingenuously* as although professing to quote textually (from page 7) six consecutive paragraphs bearing on the point, he has left out 1, and that the most important one, the back-bone indeed of what he is pleased to call "*my system*" (The Play of Hamlet in fact, with the part of Hamlet left out) *viz* that following "in a similar manner osier beds in England." "I have mentioned the latter as in order to stimulate a "rapid, aqueous and sappy growth, as also to provide for the dry "seasons common to hot countries a system of irrigation would be "necessary, such a system indeed being at present practised with the "sugarcane in Egypt, Spain, and elsewhere.

Long before my pamphlet was published however in January 1875 I addressed Dr. King requesting his advice and opinion in bamboo cultivation, and cropping, giving my views *in extenso*, and stating that I considered irrigation an essential, quoting rye grass under irrigation in this country in illustration, but to this letter I received no reply till June. In reply, having then learnt that experiments would be instituted to investigate the bamboo industry I proposed, I addressed another lengthy letter to Dr. King suggesting that *various systems* of cultivation and cropping should be tested, sending him an account of the manner in which the bamboo when cultivated for paper was treated by the Chinese from which I extract as follows:—

"To cause it (the bamboo) to produce an abundant crop for many "years, the *sprouts* must be cut some distance from the ground; if "they are cut on a level with the earth the plant would be entirely "ruined, perhaps because the shoots being entirely stripped, would no "longer be preserved from the burning rays of the sun, or because the "branches and the leaves which grow in abundance round the foot of "the plant cannot receive nourishment any longer from the air, and "have therefore none to furnish the roots."

Dr. King did not acknowledge this letter, neither did he favor me with any further communication, but as he had ample time to consider the subject before he instituted the experiments ordered by Government, which were not commenced before June 1876, it is very difficult to understand *his system* of procedure, and still more so his reasons for confining himself to "*the one single system*" which he condemned as "Utopian," as also why with that conviction he he should not have simultaneously tested at least one, if not more, of the three alternative or comparative systems recommended by Dr. Brandis even if he disdained to test the system pursued by the "poor Heathen Chinee." This however lies with him to explain.

In spite of the failure of Dr. King's experiment, I must not say experiments, *as unfortunately he only made one*, I have no fear of the future of bamboo, indeed I am glad to see from his letter that even Dr. King admits—"that young bamboo shoots may one "day become an article of export" but why he should say it would "be more profitable to growers to sell their bamboos mature, than "to dispose of them in the succulent stage" I confess I do not understand, this being much on a *par* with saying that it would pay better to sell sugarcane for chewing than to make sugar from it, or to grow asparagus or cabbages for their seed instead of eating them.

Dr. King recommends "my directing my inventive powers to utilising mature bamboo stems." Why should I do so? especially when after full investigation I have found that the young shoots are so vastly superior in every respect for paper stock, the reason of which I have fully explained in my Pamphlet, as also in my letter to Dr. King above referred to, shewing that matured bamboo stems are wood, and very hard silicified wood too, being wood, they must be treated as wood, but then paper makers do not want wood, and if they did, can procure it from Sweden and Norway nearer home, and cheaper, than importing bamboo wood from India.

I regret as Dr. King remarks "having had so little opportunity "of acquainting myself with the peculiar growth and cultivation of "the plant" I can only therefore rely upon the opinions of practical

botanists, and others, who have, and the more the question is investigated the stronger becomes my conviction that bamboo in India has a great future, and that my calculations as to the cost and facility of producing the young stems suitable for paper stock if judiciously conducted in plantations will not be found very erroneous; if collected from the native forest or jungle they would necessarily be dependent upon locality, cost of carriage, &c., &c.

I believe Dr. King has been misinformed as to the Chinese employing mature bamboos for paper, except possibly for coarse packing paper, the extract I have quoted shows the plant is carefully cultivated for cropping the young "sprouts" or "shoots," and if Dr. King had followed *their system*, instead of cutting down every stem, both old and young, as well as every twig produced, he would not have had to *chronicle a failure.*

THOS. ROUTLEDGE.

Claxheugh, Sunderland,
6th March 1879.

CHEMISTS' VALUATIONS OF MANURE.

(To the Editor of the "North British Agriculturist.")

SIR,—This subject has recently attracted so much attention that I think the following facts will be read with interest by all concerned, and may be safely left to speak for themselves, which they do far more eloquently than any amount of argument on one side of the question or the other :—

We recently received from one of our agents a complaint that some dissolved bones which, prior to their leaving our works, had been analysed by our chemist and found to contain—

20·41 soluble phosphates ;
17 08 insoluble ,,
2·68 ammonia—

had been analyzed for the purchaser by Mr. Stevenson Macadam, with the following result :—

Soluble bi-phosphate of lime	18·56
Equal to bone phosphate rendered soluble	(21·16)
Insoluble phosphate	15·52
Hydrated sulphate of lime	35 83
Alkaline salts	2 14
Silica	0·32
*Organic matter and moisture	14 88
Moisture	11·76

*Ammonia, 1·63

STEVENSON MACADAM, PH D.,
Lecturer in Chemistry.

Second-class dissolved bones and value on association standards—£6-18s. per ton cash at principal seaports.

Not being satisfied with Dr. Macadam's analysis, we requested the purchaser to send a sample to another chemist, and suggested Mr. R Carter Moffat, whose analysis showed it to contain :—

Bi-phosphate of lime	14·74
Equal to soluble phosphates	(23 10)
Insoluble phosphates	14 50
Sulphate of lime	29 40
Sand	3 12
Alkaline salts	1·23
Organic matter, water, and ammonia	37 01
	100 00
Ammonia	2 70
Equal to sulphate ammonia	10 51

Remarks.—This is an excellent manure. It is in fine condition, and contains a satisfactory proportion of phosphates (soluble and insoluble) and ammonia. It will prove a good and permanent fertiliser. Calculated value to the farmer per ton, exclusive of bags—£8 10s.

R. CARTER MOFFAT. Ph. D.,
Analytical and Consulting Chemist.

The buyer was naturally surprised upon receipt of this analysis to find two chemists differing so widely, and accordingly determined for his own satisfaction, to send a further sample to a third chemist, and he selected Mr. R. R. Tatlock, whose analysis shows :—

Bi-phosphate of lime	14·71
Equal to soluble phosphates	(23·04)
Insoluble phosphates	12·05
Ammonia	2 50
Equal to sulphate of ammonia	9 70

R. R. TATLOCK, F.R.S.E., F.C.S.

This analysis was accompanied by the following letter :—

Please find enclosed certificate for analysis of dissolved bone. Although I don't consider that it comes within an analytical chemist's province to fix the money value of the article which he analyses, I may say that a farmer should be able to purchase the manure (delivered) from any respectable manufacturer at a maximum price of £8 per ton.—Yours faithfully,

R. R. TATLOCK.

Putting all other discrepancies aside, although it will be seen they are not inconsiderable, it was evident from the composition of the manure, as well as from our own analysis and those of Messrs. Moffat and Tatlock, that Dr. Macadam had made a serious error in the determination of ammonia in this sample. We therefore wrote to him, and received the following reply :—

11th April 1879.

DEAR SIR,—I am favoured with yours of yesterday, and am perfectly certain that the results of the analysis you refer to, as detailed in my report, are correct.—Yours sincerely,

STEVENSON MACADAM.

The Lawes Chemical Manure Co.

The above is not an exceptional case, as most manufacturers can testify, and I trust that you will do us the favour of publishing it, in order that farmers may see and understand the difficulty in which a manure manufacturer is placed when analytical chemists not only make serious mistakes in their determinations, but, to use Mr. Tatlock's own words, 'Do that which does not come within their province'—*viz.*, fix the value of articles sent to them for analysis—I am, &c.,

T. ELBOROUGH,
Manager and Secretary to
Lawes Chemical Manure Co., Limited.

THE ALLEGED EXCESSIVE USE OF ARTIFICIAL MANURES.

(To the Editor of the "North British Agriculturist.)

SIR,—Professor Walley, of the Edinburgh Veterinary College, proclaims the ignorance of such men as Lord Polwarth, and other no less distinguished agriculturists, who advise increased production as one mode by which the depressed state of agriculture may be eased. Of course it is not by stating the self-evident objection, that before you can increase the produce of the land you must lay out money on it; and where is it to come from when tenants have nothing on the farm to sell, or at their bank account? It is by the consoling remark, that even though the tenants had the money it is bad policy to increase the produce of the land, because artificial manuring and artificial cultivation produces many forms of blood depravations, and deteriorates animals fed on the crops so raised, and that animals so fed on the produce of many thousand acres of land, highly cultivated, get weakened in their tissues and liable to disease. In case there should be any mistake, allow me to quote the following sentence :—' There are many thousand acres of land which could be made to yield more abundant crops, without damage either to the land itself, or to the animals deriving support from its products.' But there are many thousands more in which forced culture has been pushed to an absolutely injurious degree, not only to the animals, but also to the land.

On no land has forced cultivation been pushed to a higher degree than in the high-rented land within three miles of Edinburgh. As Professor Walley practices in Edinburgh, it is to be supposed this is the land he alludes to. Well, the produce of no land in Scotland fetches higher prices, and none is more prized by the buyer, and, I venture to say with all deference to the learned professor, the land in question produces crops which, take them all in all, are not only in quantity but also in quality unsurpassed by the producers of the lower-farmed land which he estimates so highly. Had the professor alluded to the produce of the irrigated meadows around Edinburgh, where for nigh a hundred years the older portion has been fed with the rich excreta of the inhabitants, there might have been some grounds for believing that forced stimulation has been carried too far. He, however, makes no allusion to these excessively stimulated lands, but alludes to overdoses of nitrate of soda to grass land as being productive of diabetes. To many farmers this will be news. I have often seen as much as 8 cwt. of nitrate of soda applied to grass for soiling, of course at different times, and finer, more wholesome, or more nutritious food could not be wished. If the grass was cut dry, however luxuriant, the cattle and horses throve on it when given in reasonable quantities; however large the crop, no bad effects ever followed. While I have seen from poorly grown and badly got hay, when no nitrate of soda was used, frequent cases of horses suffering from diabetes. Indeed, badly saved and musty hay of all kinds, when given to horses, are followed frequently by diabetes.

I should like to ask Prof. Walley how it happens that beautiful, long green Italian rye grass hay, which has been raised by the application of nitrate of soda, not only sells for the highest price in the market, but gives most satisfaction to the *horse-keeper?*

I should also like to ask the professor how it happens that we hear so little of blood disease from the animals fed on the produce of the Edinburgh irrigated meadows, where, if anywhere, over so long a period, such an enormous supply of forcing, stimulating manures have been applied, and where such an excessive weight of high stimulated grass is raised ?

I should also like to ask the professor how it happens that high manuring and skilful cultivation which increases the produce of the land also deteriorates the land ? and, further, how it happens that land that has been so treated fetches very much larger rents than land not so cultivated, when it is offered for leasing ?—I am, &c.,

A TENANT-FARMER AND NO VETERINARIAN.

KOTEGHUR NOTES.

SIR,—The weather has continued dry during this month. The rainfall has been very slight. We see clouds roll up from the plains but they all pass over us—being interrupted by the Hattu range—and go on to the higher ranges. We have the haze now, and while this lasts, heavy rain cannot be expected, though we shall have light showers, as the heat—the cause of the haze—prevents the clouds from descending below the (Hattu or Whartu) second range. The first day of the month was bitterly cold, but more seasonable weather soon came on. The following is a comparative table of the past five seasons :—

	April.				
	1875.	1876.	1877.	1878.	1879.
Snowy days...	...	...	...	...	...
Haily „ ...	...	...	1	4	...
Rainy „ ...	1	4	16	11	7
	Very dry and hot. Cereals suffered.	Bright and pleasant.	Very damp: ground quite soddened with the heavy wet.	Damp during first half: thunder and lightning accompanied the rain.	Dry, though very hot. Cereals suffering.

The wind has been in all quarters, not appearing to know in which one to settle for even for a short time. It very much resembled a lady going into a draper's shop to buy a yard of ribbon, she manages to turn the place upside down, and walks out without purchasing anything. When the wind began blowing the weather-wise would prophecy " Ah ! this is the right sort of breeze ; we shall have rain before to-morrow morning ; " but they were as much out as the store-keeper who expected to see the lady's coins pass across his counter, for none came.

The thermometer (Fht.) hung in an open verandah, W. aspect, is about 57° in the morning, 66° in the evening ; lowest 48°, highest 72°. Out in the sun it has reached 133°.

The catkins of the poplar (vern. *chalou*) ; the leaves of the horse-chestnut (vern. *kanúr*), and elæagenus (vern. *gihain*), oaks, chil, mulberry (vern. *chmu*), and a rhus (vern. *titri*) the latter the last tree to come into leaf—are now out. The horse-chestnut is now blossoming, and in a week's time will be in full beauty · the spikes of variegated flowers presenting a magnificent appearance ; a tree then resembles a large chandelier with its long spikes of flowers tapering up from amidst the foliage like so many wax lights. The purple coloured berries of the *Princepia utilis* (vern. *bhekul*) are now ripe, and the village children are busy collecting them to press into oil for cooking purposes. The yellow flowers of the barberry (vern. *kamashal*) ; the magenta ones of the wild indigo (vern. *loon*) . the white ones of the clematis ; the light brick-red of the wild sorrel (vern. *malera*), in which, at a little distance, looks like a heath ; the *yellow potentilla* ; the *white potentilla* ; the wild syringa (vern. *kandi*) with its delicate white flowers ; the Himalayan honeysuckle (vern. *khuati*) with its small yellow and white blossom ; the wild strawberry with its white flowers ; wild sage ; wild thyme, these and many other wild flowers too numerous to mention here are now making our fields and hedges gay with their brilliant colours. The wild roses—white and pink—are budding, and will be in splendid profusion next month. Bergamot springs up.

The monaul pheasant now becomes very shy : the argus pheasant has begun to pair ; minas are in plenty, monkeys have arrived from the lower hills and are making free with the ripening barley. The roe fish is in season, some of them 10 to 12 lbs. in weight : they sell at about one anna a pound, although travellers will be asked four times that sum.

The price of food grains is about the same kept up through the instrumentality of the Government officials who are large landed proprietors and therefore interested in keeping up the value of food grains.

The barley harvest is late this year in spite of the early and warm spring we have had ; in 1878 it was reaped on the 20th of this month, the same field will be fully a fortnight later. The villagers have sown eleusine corocana (vern. *kaoni*) ; upland rice (vern. *rause dhan*) ; paspalum sp. (vern. *kodra*), and hill dall (vern. *bhernu*). Poppy (vern. *fim*) ; and lentil, (vern. *masur*) are in flower, and being weeded ; these two crops are grown together as a mixed crop.

The fruit of the walnut, apricot, and peach are forming, the china-tallow tree is leafing. A neighbour of mine, a well-known horticulturist, is trying the experiment of growing oranges in the open air ; I doubt the success of the experiment as the elevation is too great ; the trees will thrive but the fruit will not ripen, as the extreme vertical range of the orange region of the tropics is 4,000 feet, having a southern exposure ; however, the experiment is worth trying, and if it can be made to succeed, he will do so ; and then there will be real orange blossoms for the use of the future brides of this increasing neighbourhood : I need hardly inform you that orange-blossoms are emblematical of fruitfulness, hence their appropriateness as the decoration of a bride.

Potatoes sown in October, November and December last, only sprouted this month, owing to the dryness of the past winter. Other potatoes sown last month are also sprouting, so that no time has been saved by planting these tubers in the autumn. My idea was to sow monthly from October to March as in England—so as to obtain a succession, but the experiment, from want of rain at the proper time, has proved a failure.

Single stocks ; pansies, iris, roses in profusion. Asparagus, water-cress, cress, radishes ready ; lettuces transplanted ; beans, and peas sprouting, other flowers and vegetables progressing satisfactorily.

G. P. P.

Koteghur, 30th April, 1879.

The Indian Agriculturist.

CALCUTTA, JUNE 2, 1879.

THE ETCETERA DEPARTMENT.

NINE separate departments occupy the activity of the Director of Agriculture and Commerce in the North-Western Provinces and Oudh. He has two botanical gardens, one experimental farm, one sewage farm, one horticultural garden, two tobacco farms, one orchard, one stock farm, one silk farm, and all the estates under the Court of Wards. The botanical gardens are described as a " national heirloom," and it is considered (by the Director) due to the dignity of the province that money should be granted ungrudgingly to keep them up. Unfortunately these are not days in which money is to be had for the asking, and botanical gardens must take their chance along with public works. Mr. Buck, however, knows how to work them without absolute dependence on a penniless Government. He has managed to drain the grounds with the sale proceeds of felled timber. Economy is also to be consulted in the arrangement of the gardens. " There is no public," it is justly remarked, " as in Calcutta or London, for whom to make scenic effects"; and expenditure on mere beautification has therefore been discontinued. The gardens are to serve the purpose of a collection of the products of Northern India, and also such products of other climates as can be successfully grown here ; utility, not curiosity, being the guide of choice. These however are mostly anticipations of the future. Hitherto the gardens have done little good. Saharanpore seeds have got a name for not coming up ; and Mr. Buck says he is not surprised at it. A practical gardener is wanted. The gardens enjoy the blessing of a superintendent, but it seems that he is not a practical gardener. In short, so far as regards botanical gardens, the main thing to be said is that little or nothing has yet been done. Arboriculture was supposed to be an important function, as was also the propagation of fruit trees but a more intimate acquaintance with the gardens has proved these opinions to be erroneous. " Foresters had been trained at Saharanpore, but the training was not of the kind required." No rational being

can suppose that Saharanpore will ever supply trees for the arboriculture of the province. Roads and canals are the two great spheres of tree-planting; and for all practical purposes it is much better to get young trees in the district than to send for [illegible]. If the Agricultural Department is to take an interest in arboriculture, the plan followed should be the simple one of worrying district officers till they can shew avenues of trees along all their roads. This, indeed, is an object which is worth attending to. Comfort to travellers would not be the only advantage. The country is beginning to feel the want of the groves which have been driving our railway trains so many years; and disastrous variations in the rainfall would not improbably become less frequent if denudation were steadily compensated by new plantations.

Experimental farms have this casual similarity to gardens, that their annals for the past year are a blank. "The drought destroyed the value of field experiments." It appears that the Secretary of State, when called on for practical farmers, sent out gardeners, who have been got rid of with some difficulty. "The last one, who was useless except to grow roses, resigned under compulsion, and the farm has since been under the temporary management of an indigo-planter." If, however, there are no experiments to record, one cannot complain of want of energy in the manufacture of ploughs. From America, from England, from Bengal and Madras, ploughs have been collected and collated, and two promising selections have been made. The reformation of Indian ploughing is beset by a number of difficulties which appear ludicrous, but are really formidable. Native cattle are trained to turn round in the opposite direction to that required by the English plough; and of course the share of the improved plough must be made to suit these animals' notions. Then, the cultivator prefers carrying the plough a-field on his shoulder, so it becomes necessary to keep down the weight as much as possible. The custom, indeed, is one which obtains also in countries much nearer home. It will be remembered that among the evil omens which met the Knight of La Mancha as he set out on his last disastrous expedition, one was a country-fellow going to his work with his plough on his shoulder. In India, as in old-world Italy, it is a common sight to see

Fessos vomerem in versum boves
Collo trahentes languido;

but though the bullocks always drag the inverted plough home in the evening, it would offend all rule and custom to make them drag it out in the morning. Again, the plough must be short, so that the cultivator may get at the tails of his beasts, since it is only by manipulation of this organ—wrenching, pulling, and twisting—that man can overcome the Indian bullock's tendency to stand still. Finally, it must be cheap, and adopted to a small and weak breed of cattle. All these points have been more or less provided for, except the great tail difficulty; and even this is said to have been conquered by a certain "subsoiler," the work of an ingenious Mr. Macrae. Having got ploughs, the next step is to make the natives use them. What with Court of Wards estates, and intelligent zemindars, and amateur farming Collectors, a good many ploughs have been set going already. As for what may be expected, we may quote the Director's own words: "The question [of an improved plough] is of the very highest importance to the country, if it is true that a larger amount of food-crops can be raised by its means throughout India; and I cannot but insist that the natives' verdict in this respect will be the surest. . . . It may safely be promised that they will, if the produce is larger, take to the use of any plough which is adapted to *their* labour and means." After this comes a little paragraph telling us that the net cost of the Cawnpore farm was only Rs. 1,837 in the year under report. So much can be done by zealous and clever management. Not less noteworthy in this respect is the sewage farm at Allahabad, which pays its way already, and will shortly bring in some Rs. 10,000 a year to the Municipality. Such an example cannot fail to be of value. If municipal conservancy can be made self-supporting, a most welcome relief will have been given to Municipalities, in these days when the main source of their income is threatened with abolition.

Tobacco is evidently the pet child of the Agricultural Department. Vast possibilities here disclose themselves. In the foreground of the picture is seen the flourishing cultivator; in the remote vista floats a vision of a new source of revenue; while wealthy planters and cheap cigars fill up the rest. Private enterprise is the means by which we must hope to see these good things brought to pass; and it speaks volumes for the Director's practical wisdom that he has chosen from the beginning to work the experiment through a private firm, "who, while they have connections in the trade in England and America, have not to ask the leave of half-a-dozen authorities when they want a new curer." The results are still uncertain, but general hopefulness prevails. It is necessary to remember that more than two years elapse before the crop sown is ready to do justice to itself in the home market. Patience seems to be the one thing needful. Already a few samples have fetched two-thirds the price of American tobacco, and three times that of any Indian tobacco hitherto tried. An attempt to induce the troops to use Ghazipore tobacco was not successful; but neither were the first efforts to introduce Indian beer, which now commands so extensive a market. It is understood that the new tobacco does not find encouragement in official quarter in England. There are other conceivable reasons for this than any real inferiority of the article. Moreover, it seems more than probable that a change in climatic conditions will greatly increase the chances of success. A new farm has been started near the Tirhoot frontier, in a Bengal climate, and already promises to eclipse the parent farm at Ghazipore. Experiments have also been begun in Kumaon. It will go hard if some striking results are not chronicled within the next two or three years. Kumaon has also been selected for orchard-planting on a large scale. It was Sir John Strachey who first called attention to this favoured region, while he was Lieutenant-Governor of the province. In fact, as all the world knows, the Agricultural Department was the work of his hands. The special connection of Kumaon wth this Department consists in the endless variety of soil and climate presented by those wide and picturesque highlands. Tea has already begun to rank as a staple; and Sir H. Ramsay is resolved that fruit-trees shall follow. A happy thought comes from the Pyrenees. Chestnuts provide the greater part of food there; why should they not be equally useful in the Himalayas? Apricots and apples have proved a decided success, but for want of systematic development, we have to pay sixpence a piece for apples in Nynee-Tal, while Cabul merchants can sell them *in the bazaars below* for half the price. Native enterprise is of course quite unequal to a business of this kind, where the existent demand is practically *nil*, and the returns to capital invested are problematical and distant. When Government orchards have proved that fruit-growing is a paying speculation, we may look to private enterprise to do the rest, as was the case with tea cultivation in the Dhoon. Amidst rumours of bankruptcy and distress, it is immensely refreshing to find all these new resources only waiting to be developed. Far be it from us to hint discouragement. We have faith in Mr. Buck, and believe that he is doing good and earning fame.

AIR AND WATER AS SOURCES OF PLANT-FOOD.

THERE is no such thing, in nature, as absolutely pure water. The waters of wells, springs, tanks, drains, brooks, rivers and the ocean, are charged with a great many different kinds of matter which water takes up and carries with it wherever it flows. Absolutely pure water can be obtained only by distillation; and even distilled water, if left exposed to the air, will gradually have mingled with it many substances borne by the wind and carried into it by rain. Chemists have analysed all kinds and qualities of water, and they find, that putting aside impurities, absolutely pure water can be separated into two and only two substances, which cannot, in the present state of science, be further divided and are on that account called *elements*, because nothing else can be obtained from them. These elements are hydrogen and oxygen, both of them gases at the ordinary temperature and pressure; and both very widely diffused in nature. Everything in the world, whether animal, vegetable, or mineral, is found by chemists to consist of substances which cannot be further reduced or made more simple

These simple substances of which all material things are built up, chemists have agreed to call *simple bodies* or *elements*, and the whole number of these, which science has, as yet been able to discover, does not exceed sixty-three. It has also been found that the greater part of every living thing, whether plant or animal, is composed of only four of these elements, *viz.*, carbon, hydrogen, oxygen and nitrogen. These are sometimes called organic elements ; and sometimes *organogens*.

In like manner it has been found that air, when perfectly pure, consists chiefly of the elements oxygen and nitrogen in the proportion of about one to four by bulk. These gasses are not in any way combined, they are simply mingled together much in the same way as milk and water may be mixed mechanically together, the water having no effect on the milk except to dilute it. Nitrogen acts the part of water to the oxygen of the air, dilutes it, robs it of more than half its strength. Were our atmosphere composed entirely of oxygen, the whole world and the beings that inhabit it, would present a totally different appearance to what they do at present. The circulation of animals would be doubled or trebled; muscular action and thought would be much more energetic and rapid ; and life probably worn out in a much shorter time, the vital forces would be used up by excess of oxygen. The effect of a pair of bellows on a low fire is well known. A smart current of air is forced among the embers ; and in this way a much larger quantity of oxygen than usual is brought in contact with the fire. The oxygen enters into union with the carbon, of which all fuel is largely composed, and the other constituents, forming new compounds and evolving light and heat. Like oxygen and hydrogen, nitrogen is a gas without colour, taste or smell, all are soluble in water.

The atmosphere, like water is never absolutely pure. In addition to oxygen and nitrogen there are always other substances present in larger or smaller quantities. The most important of these is carbonic acid, sometimes called carbonic anhydride and carbonic dioxide, CO_2. also a gas without colour, taste or smell, but very heavy, so heavy, that it may be poured from one vessel into another as easily as water is poured. Carbon dioxide is being given off continually from the lungs of all animals ; and wherever there is flame, it is also given off as a produce of combustion. The proportion of this gas present in the air is about four volumes in 10,000. This amount, however, is not always constant. It increases during the night ; and it is greater during dry winds and fogs, as high a quantity as eight or nine volumes in 10,000 have frequently been noticed on foggy days. Country air contains less than town air ; and sea air less than that over land. CO_2, carbonic dioxide is being constantly sent into the air by the combustion of organic matter, and the oxidation of the waste tissues of animals. Unless then, some other influence were at work, the oxygen of the air would gradually diminish and the carbonic dioxide increase. This influence exists in the power possessed by plants to decompose CO_2, carbonic dioxide, retaining the carbon, and setting free the oxygen. The oxygen serves as a carrier of one of the waste products of the tissues of animals (carbon) to plants, which again return it (the oxygen), to the air and assimilates the carbon to form fresh food for animals. A square metre of leaf surface will decompose in sun-light more than a litre of carbonic dioxide in an hour. There are other sources of this gas besides those already mentioned. Carbon dioxide finds its way into the air from subterranean sources, from volcanoes, and from caves and chinks in the earth's surface. It is one of the invariable products of the decomposition of organic substances. Besides carbonic dioxide, nitric acid or some lower oxides of nitrogen are frequently perhaps invariably present in the air. The formation of nitric oxides is mainly due to electric discharges during thunder storms. In tropical climates, these are very frequent ; and very probably much of the nitric acid found in these regions in the form of potassium and sodium nitrates has its origin in a combination of the nitrogen and oxygen of the atmosphere by means of electricity. One million parts of rain water are said to contain ·0507 parts of nitric acid. In Glasgow an average number of determination gave 2·436 in one million.

Ammonia H_3N is also present in the air. A piece of clay heated to redness and exposed to the air for a few days yields a perceptible amount of ammonia when reheated. Ammonium sulphate is in like manner converted into ammonia alum by prolonged exposure to the air. The amount of ammonia has been variously estimated. The record of registers vary from 135 to ·01 of ammonia (calculated as carbonate) in one million parts of air. The direction of the wind has no influence on the amount of ammonia. The quantity decreases after heavy rain, being washed out of the air into the soil, and thus supplying plants with an important food material. A few hours after rain, the normal amount is found, being about six parts in one million. The proportion of ammonia in rain is as various as that contained in air. The quantity is greatest in the rain that falls first :—

Rain water of		Liverpool	contains	5·38	parts.
„	„	„ London	„	3·45	„
„	„	„ Manchester	„	6·47	„
„	„	„ Glasgow	„	9·10	„
„	„	„ Paris	„	3·49	„

It is contained in the water of dews and fogs in much larger quantities than in rain water.

These amounts of ammonia and nitric acid may appear trifling small, but they are large enough to play a most important part in vegetation. They are the chief source whence plants obtain the nitrogen necessary for the formation of their seeds and other parts of their structures into which nitrogen enters as a necessary constituent. Plants do not appear to possess the power of directly assimilating the free nitrogen of the air. Indeed, if placed in an atmosphere and a soil free from ammonia and nitric acid, and from substances that produce these, plants will die. Schonbein was, we believe, the first to observe that ammonium nitrate is produced by the evaporation of pure water in air. Water is constantly evaporated from plants and from the soil and it is highly probable that in this way plants may obtain and prepare for themselves a portion of their nitrogenous food. So far as at present known, the only necessary and essential constituents of the atmosphere, are oxygen, nitrogen, carbon-dioxide, aqueous vapour, ozone, ammonia and nitric or nitrious acids. The chief function of ozone, (which indeed is but nascent oxygen, oxygen newly liberated from some of its compounds and on that account capable of effecting new combinations with greater energy and activity) is to oxidize and render innocuous the putrifying organic matter which is being constantly sent out into the air from numerous sources. No ozone can be detected in large cities, nor in the air of dwelling houses. It is not found in air over marshes or in places infected by malaria, and malarious fevers are no doubt due to the fact that the air is entirely destitute of ozone and is charged with carbon dioxide, watery vapour, ammonia, and the other products of organic decay ; and is thus quite unable to carry off from the body the effete matters cast off in the process of circulation and the action of the sweat and other glands. The waste tissue remains in the system and produces disease. The depressing effect of the air of cities and large towns is very closely related to the presence or absence of ozone and its action on organic matter.

An analysis of 10,000 volumes of pure air would give the following results :—

Oxygen	equal to	20,65·94	In 10,000 parts.
Nitrogen	„	77,90·60	
Carbon dioxide	„	3 36	
Ozone	„	·015	
Aqueous vapour	„	140·	
Ammonia	„	·08	
Nitric acid	„	·005	

The atmosphere is indeed the common sewer of the world it has poured into it night and day innumerable gaseous and volatile impurities, organic and inorganic, which the forces of Nature and the ingenuity and filth of man and modern civilisation have given rise to. The examination of rain water affords the best text we at present have, for determining the amount of impurities in the air. Rain falling through air over the sea contains, chiefly common salt and sulphates. The sulphates increase inland, and are undoubtedly the products of decomposition, the sulphurated hydrogen evolved in the putrefaction of organic compounds being oxidized in the atmosphere. When rain contains more than forty per cent. of free acids, the vegetation of the district is rapidly effected. Ammonical salts increase in the neighbourhood of towns, they are derived partly from the coal used as fuel, and partly from the decomposition of albumenoid substances. It should however be borne in mind that the bulkiest factors in pure air and pure water are nitrogen, hydrogen and

oxygen, the latter being found in both. The other substances, though comparatively small, are some of them essentially necessary for the health and growth of plants.

Rain is in reality distilled water, raised by the sun's heat, in the form of vapour, from oceans, seas, lakes and rivers, and condensed by cold currents of air, mountain ranges, and table lands. Rain in its passage through the air and the clouds as float in the higher regions of the atmosphere, sweep the whole air-ocean, like a fine net and drag to earth every compound and impurity soluble in water. In seeking its level water does not only act mechanically on the rocks over which it passes; it is perhaps the most universal solvent in Nature and charges itself with whatever substances it comes in contact which may be soluble in water.

The solubility of gases in matter is a well-known fact and it plays a most important part in the economy of plants and animals which inhabit water. Sea-water contains as much as from 2,000 to 2,800 grains of solubles in a gallon. The Red Sea contains from 11,000, to 21,000 grains of soluble matter to a gallon. The following are the chief *inorganic* matters found in natural waters. Lime, magnesia common salt, sulphates, silica, iron, iodine, nitrates, sulphurous hydrogen and carbon dioxide. Lime exists in water chiefly in form of sulphate or carbonate.

COMPARATIVE PURITY OF NATURAL WATERS :—

The Clyde	contains	8	grains of	solid matter	per gallon.
„ Thames	„	20	„	„	„
„ Dee (Aberdeen)	„	4	„	„	„
„ Seine (Paris)		30 to 40	„	„	„
„ Old City Wells (Glasgow)		30 to 100	„	„	„
„ Loch Katrine	„	2	„	„	„
„ Lake Loka (Norway) ...		½	„	„	„
„ Edinburgh	...	7 to 14	„	„	„
„ Surrey (through greensand)		5	„	„	„

EMPIRIC FARMING.

LIEBIG, in his "Letters on Agriculture" has said, that the empiric farmer is a "mere trader in meat and corn." The word empiric, like many another in the English language has fallen from its first high estate. Its early meaning was an experimentalist, a searcher after facts in nature. Gradually it fell away from this meaning, and now-a-days an empiric is one who has given up all theoretic study of a subject, and guides himself by tradition and his own experience. In medicine, an empiric is a person, who for want of theoretic knowledge prescribes remedies by guess, without concerning himself about the symptoms of the disease, the constitution of the patient, or any other of the thousand and one modifying circumstances affecting the case. An empiric farmer then, is a man whose agricultural operations are guided solely by rule of thumb. He does, as his father did before him, as his neighbours have done around him, for no other reason, than just that they have done so and been content with their results. He does not keep himself abreast of the age; and only adopts improvements, after every one else has tested and long enjoyed their benefits. He does not trouble himself about collateral matters, he seeks simply to get from his soil the largest possible crops; and he believes *that* system the best which will give the richest harvest, at the least expense, and in the shortest time. His fathers never troubled themselves about what would become of the soil, nor what effect their system of cvltivation might have in bringing about the failure and ruin of special crops, why should he concern himself about matters such as these? If he can succeed in making a comfortable living out of his land, clear his rent, his interest on capital, and a percentage for his own labour and risk of capital; then in these results he has a proof, conclusive enough to him at least, of the wisdom and soundness of his system. When he finds a falling off in any of his crops, he tries whether growing other varities will not answer better, and gives all sorts of curious reasons why the soil has diminished in fertility. Its because the wood has been cut down, or the railway (narrow guage) has passed near his land—its the growth of the neighbouring town "as does it," its the thunders storms, of last year, its the land-tax, and the Famine Commission!

If insects attack a crop and threaten its destruction, he will believe everything and anything; but it requires little short of a surgical operation to get the fact into his head, that it is his own ignorant wasteful parsimonious treatment of the soil that is at bottom the cause of many of his ills. He never attributes this falling off to his methods of culture. In fact the idea that he himself may be in fault never occurs to him. He is, as Liebig calls him, a trader, merely, he knows indigo, tobacco or tea when he sees it; but he has no hold whatever on the principles underlying the growth, nutrition and economic production of the very commodities he trades in. He is not even grateful to the chemist or scientific man who puts into his hands a mineral or a bone soluble phosphate, who furnishes him with the principle that enables him to produce crops under conditions that will not violate and defy the very laws of their production. It may be, he tosses his phosphates on the soil without knowing more of their *composition* and effects than his own coolies or cow-boys; and thinks what a clever fellow he is when he applies nitrates, and uses appliances and methods which the scientific man whom he sneers at, has put into his hands and taught him how to use.

He is no agriculturist, but a mere fumbler and a stirer of the soil, if he has never enquired whether the system he follows is in accordance with well established truths and natural laws, or is in any way opposed to them. The rational agriculturist should never lose sight of the fact that his efforts should be directed not to the present production of the largest crops, but to an indefinate recurrence of such crops, as long as the soil and the crops receive rational treatment. The land of central Germany, the grass lands of Cheshire, and the soil of southern America, were all of them treated in such a way by their ignorant and rapacious owners, that every available particle of plant food was drained out of them, and the crop would scarcely grow seed enough for next year's sowing, much less pay for the labour of working it. Tons weight of mineral matter cannot year by year be removed from land in crops, without diminishing and at last exhausting the active, soluble substances, without which no paying crop can ever be grown. If immense quantities of plant food are removed from the land by successive harvests without any attempt to replace the loss by the natural means of fallowing and thus allowing time for the various agencies of disintegration, decay and the action of the various forces which render the dormant substances of the *soil active, that is* change the insoluble into the soluble, or by the substitution of a crop which requires mineral matter of a different kind to that of the preceding crop, if there be neither fallowing, rotation, nor manuring, then there is nothing for it but a speedy looking for of failure and disaster, as the worm turns on the foot that crushes it, so certain plants for a time will bear the most brutally gnorant treatment, expending their whole vitality in reproducing their kind, in seed bearing, till at last Nature revolts and turns on her destroyer, the crops falls and the tormentor is punished. These are elementary truths but they lie at the root, of most failures of crops and blights and insect pests and other ills that vegetable life is heir to, and need to be reiterated and repeated like the commonplaces of morality and honest dealing.

THE GRASS LANDS OF THE NEILGHERRIES.

THE future of the Neilgherries, especially the grass lands, depend on the intelligence and pains with which all the details of cultivation are carried out. The climate is excellent, and tea and cinchona promise good results, if the proper means are observed. Much of the grass land, on the plateau, contains plant-food for many years without manuring, *if lime is* judiciously applied. Rich forest lands may in some measure defy the efforts of the planter to produce failure, but if he opens up the grass lands in question in a slovenly unscientific manner, the proprietor's patience will be taxed as he waits year after year for his overdue produce. Let any man of ordinary intelligence run through the several tea and cinchona gardens on the Neilgherries, and he cannot fail to gather in what I mean. In well-selected parts he will find eighteen to thirty inches of vegetable mould on the surface, evidently the decay of vegetation for ages. This humus unlike that generally found in sholas and forests has been, by exposure to alternate rains and sunshine, beaten

down and baked into so compact a mass that rain and air cannot penetrate so long as the soil is left unworked, or is worked without judgment. The baking of the surface by the sun's rays has been augmented by the annual burning of the long indigenous grass, by the Todas from time immemorial, so as to insure a successive growth of tender shoots for their buffaloes. The vegetable mould is friable and free from clay, but yet so compact and bound together by myriads of interlacing grass roots that no tea plant has a ghost of a chance until the soil has been thoroughly broken up and exposed to the weather. I know one or two plantations where the planter seems to have called upon Nature to do almost everything. The result is stunted growth with evils innumerable, which no after effort can counterbalance. Some estates are prosperous enough, but others are monuments of shame to those who had the opening and management of them. I remember the same sort of thing in Ceylon, so far back as 1848, where soil and climate were hopelessly beaten by careless and slovenly cultivation. The grass lands of the Neilgherries, if properly treated, are richer in plant-food than one-half the forest lands of Ceylon. In a block of 1,000 acres as in Ceylon, there may be 25 per cent., that no judicious planter would cultivate with tea or cinchona. He would fill in such portion with some of the Australian guano, accacias, or wattles, not the silver, but the golden or black, the bark of which have a commercial value. The man who selects bad land because it is cheap, or for any other reason, flies in the face of difficulties, but the man who refuses to buy 1,000 acres because only 750 are worth planting is not necessarily judicious. A golden rule is to skip all patches of land, that, at a glance, are not worth a generous outlay. Never run the risk of taxing a good acre of tea with the up-keep of a bad one. This is a rock on which many a planter has wrecked himself. The buyer of grass land has one advantage over the buyer of forest. Observation, during a week in the windy season, will reveal whether the wind cuts the estate, and where. No amount of observation will reveal this correctly on forest land until the timber is felled. If grass land is found to be raked by eddies and blasts of wind from all quarters, the would-be purchaser will be wise if he leaves it alone, but after forest is bought and opened it is not so easy to do this. I prefer land, over which the wind sweeps in one direction. Ridges may be planted out with gums, and form effective break winds for the whole estate, warming the atmosphere and fostering vegetation.

Years of observation convince me that planters, as a rule, have been making a grand mistake in treating rain as "an enemy," instead of "a generous friend," to be got rid of at any price and in the most expeditious way. Weedy estates, weeded by the *mamotie* was one cause which forced this upon planters. As soon as the monsoon rains set in, they saw the loosened surface soil carried away by the rainfall into the gullies, and away to the low country, exposing the roots of the coffee or tea trees. Then came the remedy, drains and cross drains at various distances, and at various gradients. If the gradient was steep the remedy was as bad as the disease; and if the gradient was slight the drains choked. On the grass lands of the Neilgherries, I look upon the retention of the rainfall as a cheap and valuable fertiliser. To cinchona it is silver, to tea it is gold.

What does the rainfall do? I answer, only a minimum of good if the planter runs it off his land as soon as it falls. Luckily for himself he cannot prevent the plant from taking in some of its benefits as it moistens the foliage and the surface roots. I have seen the monsoon rains fall on estates, the surface of which were as hard as a pie crust, and as rain from a duck's back so did the water rush off the slopes and hills. On the other hand I have seen such rains carry off the loosened soil in tons, taking the easiest channels, and leaving little or no benefit to the estate. My anxiety is to induce the soil to retain every drop of this rainfall. I shall not succeed, but I intend to do all I can towards that end. The sub-soil, insures permeation, and I look for most favourable results.

Firstly. The rain will carry with it, not only to the surface roots, but to the roots below, even to and beyond the extreme end of the tap roots, the fertilizing substances met with and brought down with it from the air, such as ammonia, nitric acid and saline matters.

Secondly. It will soften, dissolve, and distribute the plant food it finds in the soil itself, and allow all the roots of each plant to absorb it.

Thirdly. It will, especially when alternating with sunshine, warm the under soil, stimulate the growth of the plant, and in years to come keep up a succession of flushes after every shower. The sun's power cannot effect the temperature far below the surface, but, with the soil judiciously prepared to receive the rain, every shower will carry down with it, to the roots of the plants, the warmth from the surface and so equalize the temperature.

Fourthly. In cases where the subsoil holds an abundance of iron or other noxious matter, the rainfall will serve to carry these further down and out of the reach of the plants.

We may now consider how the rainfall can be kept on the ground and be induced to enter the soil. In doing so, we must not lose sight of the maximum of benefit at the minimum of cost. Three method's present themselves to me.

Firstly. Supposing the width of the rows to be 4 feet apart, run *level* terraces 4 feet wide round the hills and slopes, and insist on their being level. Then trench 18 inches by 12 down the middle of each terrace, such terraces having a gentle slope towards the centre. The cost may be lessened by holing instead of trenching if the tea is planted three feet apart or upwards. Terracing, on average slopes, would cost about Rs. 35 per acre, and the trenching in the terraces another Rs. 50, giving 3,630 lineal yards to the acre. Holing 18 inch square pits would cost Rs. 13½ per 1,000. But let no one act upon the idea that the tea plants may be dibbled in. The soil in the Neilgherries will resent any such off-hand treatment.

Secondly.—Abstain from terracing and open up level trenches as above directed filling in only to the level of the lower side, which should be 18 inches deep, and the result will be a trench 18 inches deep, with a terrace 12 inches wide, every 3 feet. This should not cost more than Rs. 60 per acre.

Thirdly.—Hole on the level as in trenching, not up and down the hill as is usual, say 18 inches square holes at any distance required, say every 3 feet, then from hole to hole cut an 18 inches terrace sloping it in towards the face of the hill. The holing would cost as above stated and such terracing 12 annas per 100 yards, that *is*, if 4 feet rows be observed, 3,630 yards per acre, less one half already cut by holing 18 inches out of every 3 feet, say 1,815 yards at a cost of Rs. 13-9-9.

The first method is the most thorough, and the question turns upon the expense. The second method is efficient, and when tea plants are planted 2 feet apart, requiring 5,445 holes per acre, it is a cheaper than the third method. But when distances are increased to 4 by 3 and upwards, then the third method rapidly gains advantage, in the matter of cost. I should plant cinchona, the condeminia, 5 by 4 on the third method, say 2,178 holes at Rs. 13½ per 1,000 equal to Rs. 28-12-6 plus the terracing between Rs. 13-9-9 total Rs. 42-6-3 per acre.

Whichever method is chosen, the work should be done immediatly after the S.-W. monsoon, so that the soil may remain exposed until May, when the filling in must be done for June planting.

Many a planter will be horrified at not having regular lines of trees so as to facilitate weeding contracts, as terracing on a level round hills and slopes must necessitate short lives. But as I advocate cinchona belts all over a tea estate, cutting it up into 10, 15 or 20 acre plots, the weeding may be contracted for by the plot. The atmosphere in a tea estate should be kept warm and forcing, and I think close belts of cinchonas would effect this. In the middle of such plots I would recommend that 30 to 40 feet square patches should be left for heaping the grass roots and weeds on with a sprinkling of lime or other material for future use. Peat is very generally found all over the Neilgherries. Some agricultural chemists tell us that a bushel of charred peat is equal to a cart load of farmyard manure, if so, there is an inexhaustible supply of leaf giving manure at hand.

In conclusion, let no planter wed himself to any one or two schemes, however valuable they may be. In order to command success, it is necessary to work out every detail with thought, intelligence and economy. On the Neilgherries, it seems to be the

custom to contract for work or an article, and accept from the contractor as a matter of policy, work or material 25 per cent. in value below the thing stipulated. This is a vicious practice, and should be abandoned.

I may remind those who think of planting tea or cinchona on the grass lands of the Neilgherries, that they escape the expense of felling, lopping, burning and clearing. Further they have no roots of trees to contend with in terracing and trenching, so that they can afford a liberal outlay in working the soil so as to prepare it for the plants, and secure it against wash.

EDITORIAL NOTES.

THE Italian Government two years ago offered 3,000 lire for an essay "On the genus *Citrus*," but the productions sent in held by a special commission to be undeserving of the prize. Considering that the reasons still exist for which it was thought very beneficial to encourage a complete study of the physical nature and biology of the Hesperidæ, and for which the competition was instituted, a Royal decree has been issued offering a reward of 3,000 lire to the author of the most complete and best monographic essay on the structure, the vital functions, and the diseases of the acid fruits, or species and varieties of the genus *Citrus* and kindred genera, provided that the said work, by a sufficient collection of original observations and experiments, should succeed in furnishing an important addition to the present knowledge concerning such subjects, and thereby supply a scientific criterion for the improvement of the cultivation of these acid fruits and for the cure of their diseases. The date for sending in the works competing for the said prize is fixed for the end of May 1881. Essays by Italians, or by foreigners, written in Italian, are admissable to the competition, but if written in another language they must be accompanied by an Italian translation.

THE figures for plantation coffee to the 19th are 574,000 cwts. but native is so low as 30,000. The total exceeds 600,000 cwts. so that we suppose a total for the season ending 30th September of 800,000 cwts. may be reckoned on. There are large figures for baled cinnamon, 696,000lbs. but there is a great falling off in chips. Cocoanut oil is very considerably above the average, the export being 111,679 cwts.; ebony is up to nearly2 1,000 tons; and cinchona bark now counts 101,169lbs. The railway traffic to 6th April shews 46,742 tons of coffee against only 35,005 in corresponding period of 1878; but there is a falling off in both rice and manures—It is not to be concealed that the general feeling in Ceylon is one of depression and anxiety. But there are many elements of hopefulness in our position, and a real beginning with railway extension would contribute much to the restoration of cheerfulness and activity.—*Ceylon Observer.*

FOR the safety of many towns and villages, the raising of mountains to counteract torrents has become a necessity in certain parts of France. The idea appears to be exploded that the felling of forests has no influence on inundations. Planting trees according to climate and altitude, and inducing grass to grow, are the measures adopted by the French Government. The aim is, to anticipate the promotion of destructive torrents by consolidating the soil, and suppressing the effects of torrents by drying them up. It is not intended to actually abolish the torrent but to cause it to pass into the volume of a stream, to prevent its carrying down earthy matters, and producing sudden floods. By protecting the soil against the mechanical effects of rain, by regularising the currents, by dividing them, inundations can be avoided. For the temperate zones of mountains, the trees to be selected can afford no difficulty, but for Alpine regions only spruce, larch, and fir can be chosen—and larch above all, as it admirably resists atmospheric influences, requires no support adapts itself to all soils, and has the faculty of throwing out new branches from old bark. Except in elevated regions, it is an open question whether the plan of sowing or planting ought to be preferred. In any case when the latter is adopted, the trees cannot be too young.

MR. E. C. RYALL, in his report gives a good deal of information about the trade carried by Bhotias and Bashahris between Tibet and India. First in quality amongst the imports into India comes gold dust from the mines of Gartok and elsewhere in Tibet; but this item may be almost set aside, for most of the gold goes to Lassa, and very little finds its way southwards over the Himalayas. The importation of shawlwool, *pashm*, is declining; the demand at Delhi and Rampore being now much less than in former days. Large quantities, however, are still taken to Amritsar, Ludhiana, and Nurpur. The Bhotia traders say that if they could only find sufficient sale for *pashm* in the North-West Provinces, they would care less about the decline of the borax. trade, indeed would give up carrying borax altogether. The finest Tibetan *pashm* is grown in the neighbourhood of Lake Mansarowar, and the bulk of it is taken to Gartok, where Cashmeree merchants from Ladakh buy it up for the Cashmere manufactories. Large quantities of tea from Lassa are taken to the Central Asian markets, Ladakh, and Cashmere, but very little is brought to India. Some comes to Amritsar and is consumed by the Cashmerees living there; some is bought by the Bhotias who prefer it to the Indian varieties. Tea in Tibet is a Government monopoly. Eight kinds are sold in Gartock, all coming originally from a place called Darchando in China. The price ranges from Re. 1 to Rs. 8 a pound. There are strict rules against the import and sale of Indian tea; still, however, the Bhotias carry small quantities which they manage to sell to the poorer class of nomads. Besides the prohibition, the prejudices of the people are against the consumption of Indian teas: all Asiatics, and a good many Europeans, much perferring the China teas. Horses are brought, by the Bhotias and Bashahris, from Tibet to the Indian hill stations; those from Chumurti being the finest. Of shawl-wool goats, some three or four thousand yearly are brought from Tibet, and mostly sold to Hindus for sacrifice, fetching a rupee or two each. The quantity of sheep brought would be greatly diminished were there a larger demand for wool in the North-West Provinces. Salt and borax are found abundantly in the neighbourhood of the Thok Jalung gold fields. These articles are taken into Hundes and thence sold or bartered for grain by the Bhotias. Of imports from India into Hundes and other parts of the Tibet, there are food-grains, chiefly wheat, barley, and rice; raw sugar and spices: broadcloths, cotton goods, indigo and precious stones. Broadcloth, worth in the Delhi market Rs. 1-4 to Rs. 4-8, meets with a ready sale at Lassa, as also all kinds of cotton goods. *Ghara*, the coarsest kind is used for making flags, which are set up over tombs, monasteries and hill-tops, to scare away ghosts and demons. For indigo there is a lively demand in the markets of Shigatse and Lassa. Precious stones, such as turquoises, a few rubies, and sometimes emeralds, with corals and pearls are carried into Tibet; corals and pearls being especially affected by Tibetan women. The silver coinage of British India is much used too for purposes of ornament; but the supply is not equal to the demand, the Bhotias finding it pay better to give grain in exchange for their Tibetian purchases.—*Himalaya Chronicle.*

G. P. B." writes to the *Pall Mall Gazette*:—In these days of trade depression and high cost of provisions of all kinds I wish that the attention of the poorer classes could b directed to the eligibility of dates as an article of food at onc cheap and nutritious. Dates are extensively consumed by th lower orders in Egypt, as also by the Arabs in the Persian Gul and on the Shattu-'I-' Arab beyond al-Basrah, with whom date and bread form their principal diet. Those in better circumstance cook them in different ways, such as frying them with a littl *ghee*, or made into an omelette with eggs; and I can myself vouc for the savouriness of such dishes. Formerly, the only date imported into the London market were those from Egypt, calle Tafilat, which were and are still sold by grocers at from 8*d.* to 10*d* per pound. But the Tafilat, albeit a large and fine-looking *fruit* have a tough skin, and are far less succulent and nutritious tha those now brought from al-Basrah and the Persian Gulf. Thes latter are disposed of wholesale in boxes or straw sacks, at fro 10*s.* to 14*s.* per cwt. and hawked about the street for fro 2*d.* to 4*d.* per pound. A more general demand for the fruit woul probably lower the retail price, and it would be a great boon the poorer classes if they could be convinced that one pound c dates, costing about three halfpence, contains as much nutrimen as half a pound of meat, and much more than the same weigl of many of the articles of food for which they pay six or ten time the price.

The utility of the common owl as a destroyer of vermin is scarcely likely to be called in question at the present day. A remarkable instance in point is recorded by Herr Grote in the *Journal* of the Hanover Agricultural Society. Last year this gentleman discovered in his garden an owl's nest built in a hollow tree. When first observed it contained four eggs the bodies of seven field mice. On the following day six of the mice had been devoured and eight fresh ones introduced in their place. On the third day six more mice were added to the stock, and the carcasses of seven more were found in a contiguous hollow tree. Day after day the same thing was observed, a fresh supply of mice being constantly introduced. From circumstances which are not specifically mentioned, Herr Grote was only able to continue his observations for a period of fourteen days, but within this time the number of mice found in and around the nest was ascertained to be more than two hundred, and in addition to these the wing-cases of a large number of dung beetles (*Scarabœus stercorarius*) were found in the same place. In order to avoid any source of possible error in his computation, the observer took the precaution of marking each day's supply of mice when first noticed, so as to make quite sure that none of the bodies should be counted twice.—*Farmer.*

An interesting series of experiments were entered upon last season by the Superintendent of Cotton Experiments, in Scinde. These extended over cotton, bajri, sorghum saccharatum, jowri, lucerne grass, jute, rhea, prickly comfrey, ground nut and sundry other articles, but we are sorry to state that we can make almost no use of the report, kindly sent us by the obliging Assistant Secretary to the Government of India, Department of Revenue, Agriculture and Commerce, (Statistical Branch), on account of want of uniformity in the mode of conducting them, for instance, after an exhaustive report, explaining why the contiguous plots gave such diverse results from the same class of treatment, we find he following explanatory note. "I do not think that from this "one experiment it would be safe to conclude that the lime was "decidedly injurious to the crop, a good portion of the difference— "nearly 23 per cent. at least—may safely be attributed to the "natural difference in the fertility of the plots."

This system of experimenting is fatal to that authoritative conclusion which should be deducible from any well conducted experiment. Conditions at starting should be precisely similar, else the conclusions cannot be comparable. The Superintendent promises to continue them this year under a better system.

Referring to Jersey cattle the *Journal of Agriculture*, (American), says that their milk produces from 21 per cent. to 56 per cent. by weight of butter. In this country we think we do well if we get one chittack per seer, which is 6¼ per cent. Of course we know that the grasses of India may not be so nutritious as those of some of the virgin States of America, but still we think that judicious feeding might do much to improve our supply of butter. In Calcutta alone there is a large demand for it, and it is an article that people would not grudge to give a good price for, provided they got it good, we have ourselves made 3¼ chittacks of good butter from each seer of milk, this equals 20 per cent. We adopted the home plan of collecting cream, and making the butter daily from this cream, the native habit of churning the fresh milk does not produce nearly so much butter, nor is the quality so good. There is a good opening, we consider for a dairy farm in one of the suburbs of Calcutta where a good supply of water was available.

The *Gazette of India* contains a "Report on the Adminis-"tration of the Department of Agriculture and Commerce, "N.-W. P. and Oudh for 1877-8" and an exceedingly interesting document it is.

Mr. Buck having been asked by Government whether the expenditure of the Saharunpore experimental gardens could not be cut down, objected to such a saving being effected at the expense of the usefulness of the gardens and the Lieutenant-Governor upheld the plea, we think is a step in the right direction. There are some public works which pay their way, but an experimental garden or farm is surely not one of them. This is the rock at which many of these model farms have split. They have been expected to pay their own expenses.

The report is very interesting as indeed is everything with which Mr. Buck has to do, but it is more than this, it is instructive, and thoroughly practical. One portion of the report we endorse very heartily, and that is the desirability of establishing a farm somewhere for the express purpose of improving grain for seed purposes. Any one who has travelled over the length and breadth of the land must have seen incontrovertible evidence that poor soil and want of proper cultivation were not the only causes of the paucity of crops. There are various others, and among them bad seed. At home a farmer does not use seed grown on his own land, he prefers to purchase from a neighbouring country it may be, at least he likes a change. Here the same seed is used year after year and century after century on the same field most probably, and this coupled with the other drawback, to successful cultivation so much in vogue here, lead to what we see going on around us, a steady but sure decay in the quantity and quality of agricultural produce. The same remarks apply to cattle breeding, which subject is also touched on in the report under notice.

We are sorry that the Government of Madras has not seen fit to agree to Mr. Robertson's proposal of a series of small prizes, for well-managed farms. We do not refer especially to what he speaks of as the Irish system, but of any system suited to India. We think a few small local exhibitions, where such prizes were given would have more effect with the ryot than half a hundred circulars from the collector *sahib*. A couple of years ago there was an exhibition in Rajcote, Kattywar, which we believe was a great success, and who can gainsay the good that is likely to result from the meeting at Songad, also in Kattywar, under the auspices of Major Nutt or of the Bulandshahr agricultural show and horse fair.

These are the class of meetings that are wanted, not grand exhibitions, at which the humble ryot is afraid to appear, but smaller meetings where he will meet generally his own class, and where he will see for himself what others are doing. These meetings supplemented by a few small money prizes are calculated to spur the cultivators to greater exertions.

From a perusal of the report on wheat cultivation in the Punjab for 1876-7, which has just reached us through the courtesy of the Secretary to the Financial Commissioner, Punjab, we find that looking at the subject from an "average" point, the Punjab is not so far behind other countries. True she is a long way behind Great Britain in the matter of yield, but Great Britain expends a deal on high cultivation, which the people of India could not afford to do, but when we compare the outturn per acre with that of America with its comparatively virgin soil, we see how the case stands.

The average production in the Punjab per imperial acre was 800 lbs., and we find that while in America; some States produce 40 bushels, the average is not over 15 bushels of 60 lbs. equal to 900lbs. From the statistical table in the report we find the outturn per acre running from 3·36 maunds in Sirsa to 16·33 at Jullundhur. From Jullundhur we note that it costs Rs. 1-2-0 to convey this wheat to the nearest seaboard, Calcutta or Kurrachee. This charge is equal to Rs. 31-8 per ton or Rs. 6-11 per quarter, and is a very high charge for transit, although it must be borne in mind that the distance it has to be carried is not less then 1,193 miles.

This leads to the question as to whether it would not be advisable to the Railway Companies running heavy goods trains at very cheap rates, and without any particular regard to speed. We suppose a speed of ten miles an hour would suffice for such a traffic. The consumption of coals would be light and the general expenses trifling. Now that the Indus Valley and Kurrachee will be disputing the palm for the grain traffic of the Punjab, it behoves the East Indian Railway Company, to bestir itself, besides the Rajpootana line by Baroda will be making

a bid for this traffic shortly, all these ports of embarkation Calcutta, Bombay and Kurachee have their advantages, and that one will get the traffic which offers, most and greatest inducements.

EXPERIMENTAL FARM :—We have stated before in these columns that the Local Government had decided on selling this farm. The subject has formed matter of correspondence between the Commissioner of the Nundidroog Division and the Chief Commissioner, and the following is the determination arrived at by the Government :—It is obvious that before the Experimental Farm lands can be advantageously disposed of either by sale or lease, it is necessary to settle once and for all the question of the proper kodi level of the Sonakal tank; at present that level is so high that much of the farm-land is subjected to inundation. The Chief Commissioner desires therefore that the Officiating Commissioner will at once place himself in communication with the Chief Engineer, and that these officers visit the spot in company with the Deputy Commissioner of the Bangalore District and determine whether the waste weir level of the Sonakal tank cannot be lowered, sufficiently to obviate flooding the land of the Farm above it, without detriment to the cultivation carried on below, or if one or other must suffer, whether it would not be better to lower the level, and compensate the occupants of the irrigated land below for their decreased water supply. As soon as a decision is arrived at, upon this matter, the Farm should be advertized for sale *en bloc*, the date being fixed on the earliest day practicable with regard to giving due notice of and publicity to the intention to sell. In any case the date of sale cannot be later than the end of May, and if the Farm cannot be disposed of by sale by that date, the Chief Commissioner will be willing to lease it. The Farm and the buildings on the Farm will be put up in one lot, the implements will be sold separately, and an upset price representing the full value of the land should be placed upon the Farm, as the reserved price, under which it will not be sold. The land both in quality and situation is no doubt of value and will increase in value, and it should not therefore be sacrificed. In the event of the Farm being sold, the disposal of the house now occupied by the Superintendent will be next considered. The Chief Commissioner cannot accede to the offer made by the Roman Catholic Mission which the Officiating Commissioner forwards in the above letter.—*Bangalore Spectator.*

EXPERIMENTS are being carried out at Roorkee with the view of testing formulæ at present in use, and investigating the laws of the motion of water; a correct knowledge of these laws is essential to hydraulic engineering, and especially in the branch of that science relating to irrigation works, for on this depends the correctness or otherwise of the engineer's calculations, whether as to capacity for his channels and masonry works, or as to the amount of revenue to be derived from the use of the water.

The formulæ at present in use are based upon experiments with small volumes of water, and, though correct as far as they go, it has long been recognised that they are more or less untrustworthy when applied to the motion of large volumes of water, such as have frequently to be dealt with in practice, and that they do not fully meet the varied circumstances of slope and nature of beds of channels met with in works of this class.

The Government of India possesses in the Ganges canal and its works, more especially in the Solani aqueduct at Roorkee, opportunities of carrying out experiments of this nature such as no other Government can command, and the results of these experiments will be alike useful to this country and to the rest of the civilized world. The conduct of the experiments has been entrusted to Captain Allan J. C. Cunningham, R. E., an officer of high scientific attainments. His investigation and reports on the subject have already attracted favourable notice in European scientific circles.

The financial arrangement sanctioned to meet the cost of these hydraulic experiments, were recently reported to the Secretary of State who, in reply, has written : "The great professional and "financial importance of these experiments in respect to irrigation "in India is forcibly dwelt on in the correspondence forwarded "with your letter, and I approve of the aid your Government has "afforded from Imperial Funds for their prosecution."

MR. ROBERTSON, M. R. A. C., Superintendent of Government Farms, recently submitted for the information of the Madras Government two pamphlets received from Professor Baldwin, the head of the Agricultural Department of the Board of Education in Ireland, on the subject of improving the agricultural practice of small farmers in Ireland. Mr. Robertson remarked that the prize system in augurated by Earl Spencer, K.G., seems to have been fully successful, and efforts are now being made to extend its operations to the whole of Ireland. "In many respects the condition of agriculture in Ireland resembles the condition of agriculture in this country, though of course the agriculture of Ireland is greatly superior. I possess a considerable personal experience of the circumstances under which agriculture is practised in Ireland, and have acted as judge of farms in connection with the North-East Association of Agriculture in that country, which began some time ago to offer prizes for well-managed farms, though its operations did not extend to such small holdings as does Earl Spencer's system. And I am of the opinion that we might in this country with advantage adopt a prize system in endeavouring to promote good farming in this country. Of course the Irish system would not be adapted in its present form for the requirements of agriculture in this country; however, the needful modifications can readily be made. It will afford me pleasure to submit definite proposals, say for one Collectorate only at present." The Board of Revenue observe that the prize system in Ireland was worked in connection with a ready-formed machinery, namely, agricultural schools and school-farms such as were proposed in the Board's Proceedings of 13th December 1877. The Government have as yet passed no orders on those Proceedings, owing apparently to doubts as to funds, but the Superintendent's letter and enclosures will now be submitted to them, with the remark that trial of the prize scheme must await the introduction of school farms. Mr. Robertson's proposal seems a practical one, and likely to lead to good results, but the Government consider it "premature."

WE understand that the Scotch Company who purchased Messrs. Nicol and Co.'s concessions in the Wynaad, have engaged the services of an experienced mining engineer, who is shortly expected to carry out the prospections, and to arrange for commencing operations on a large scale.

NOTWITHSTANDING the fall in the price of food grain in our market, as well as in the Mofussil, the British India Company's coasting steamers are steadily working in the grain traffic, every steamer from the north brings in a fair quantity of grain, and for the past month about 17,000 bags of grain, have been landed, consigned solely to native merchants in Madras. From the mofussil there is grain daily being imported, and our market just now is very fairly stocked. Local quotations on Friday for first sort country rice is $7\frac{1}{2}$ measures per rupee, and ordinary rice 8 to $8\frac{1}{2}$ measures per rupee; paddy, ragi, cholum and cumboo are sold at 15 to 16 measures per rupee.—*Madras Times.*

THE intimation Mr. A. Cooper Abbs, Attorney of the Madras High Court, and Advocate in the Mysore and Coorg Courts, gave some days ago in the *Madras Mail* that he will be under the necessity of bringing a civil action against the Coorg Government, is soon to be realised, for we learn from Madras that this gentleman and Mr. Grant, planter, Neilgherries, have jointly issued a legal notice to the Superintendent of Coorg, that within two months from the period an action will be instituted before a competent Civil Tribunal for the recovery of Rs. 3,000 odd. The facts connected with the affair appear to have been as follows :—Mr. Abbs, after seeing an official notice in the Mysore *Gazette* to the effect that certain lands were to be put up for public auction, in due course bid for the same, and bought them up. He also purchased another piece subsequently, but on a survey taking place, it was found that Piece No. I was included in Piece No. II, so that, according to Mr. Abbs, he has paid twice over for the same thing. On his applying to the Superintendent for the return of the money overpaid, it was refused, and hence the proposed suit. What are the grounds on which Government refused, of course, are not known at present, but the Revenue authorities must know what they are about.

COMMUNICATED AND SELECTED.

MR. MECHI ON THICK AND THIN SOWING.

FROM the veteran owner of Tiptree Hall we have been favoured with the following:—

I have always said that this is a question depending on soil and climate, and that each farmer should, by comparative experiments, arrive at the most satisfactory conclusion. When I first farmed here, some 35 years ago, I tried 1 bushel of wheat per imperial acre against the 2 bushels usually sown hereabout, and found that the 1 bushel gave me an advantage of 30s. per acre; so I adopted it. I did not find much difference between 4 and 5 pecks. I have grown just as much from 2 pecks, and even from 1 peck per imperial acre; but to make sure, I drill a bushel at nine inches from row to row, because I am enabled to horse-hoe on the 9 inch spaces; and a man and pair of horses can do 12 acres per day. Where I do not horse-hoe, I sow the same quantity of seed with 6 inch intervals. My usual drilling of barley is at 6 inches from row to row, and 6 pecks per imperial acre. I have grown just as much from 1 bushel. Of oats (Tartarian), I drill 8 pecks per imperial acre, at 6 inch intervals; and have frequently grown 88 bushels per imperial acre—in one instance 104 bushels. In fact, I have found even 2 bushels to be too thick, and have suffered injury by premature laying in a summer storm. I attach much importance to a standing crop, which only gets bent or partially laid when ripe. Thickly sown crops, on well-farmed land and suitable climate, get prematurely laid, and in consequence get inferior as grinding barley, and thin oats, and small-headed wheat.

In 1868 (a fine season), my wheat crop averaged 56 bushels per imperial acre—one field yielding 64 bushels. Of barley (after wheat), I frequently got 7 quarters, of malting quality.

Early laid crops shut in the damp from the earth, and thus encourage the under-growths of clover or weeds. In a fine upstanding corn crop air circulates freely, green vegetation is checked, and we get large ears and kernels, and stiff, glossy straw.

The only excuse for thick sowing is a late district. No doubt thick sowing hastens the harvest, because prematurity is earlier than maturity. Wheat, oats and barley should give a return of 40 for 1. The person who sows 12 bushels of oats per Scotch acre should therefore get 480 bushels per Scotch acre. Does he do this? If so, I should be very much astonished. I could hardly believe that any farmer wasted so much money in seed; but I am bound to believe what I read in the *North British Agriculturist*.

In our southern climate I know that very thick sowing robs many a farmer.

J. J. MECHI.

Tiptree Hall, April 14, 1879.

P. S.—In our county we use the drill for sowing; very little broadcasting is done.

J. J. M.

—*N. B. Agriculturist.*

CONTINENTAL AGRICULTURE.

IN the new law in course of being voted on popular education, the teaching of agriculture in the rural national schools will be obligtory, and will at once take effect. This is going a little too rapidly; most of the country school-masters are not prepared to impart the desired instruction; all that can be reasonably expected from them is, that they prepare themselves, as well as their pupils, by means of judiciously selected treatises on rural economy. Later when the Normal Schools are inaugurated, and masters duly trained, greater results can be demanded. Each department is to have its Normal School, to which an agricultural professor will be attached; fifty professors are required, and six years are allowed to execute the programme. The supply of suitable candidates for these chairs of agriculture is at present very limited; in time, the superior agronomical colleges will meet the demand. The new professors will be required to hold conferences for the benefit of the surrounding farmers, as well as to impart instruction in the Normal Schools, hence a special tact is necessary for attracting adult attention. In the agricultural school of Ecully, near Lyons, advantage is taken of the Rhone to teach fish culture. Many farming societies give prizes to the proprietors of oyster beds and fish ponds.

It is no secret that good horses are not on the increase in France; many departments, famous for their production of horses, have to-day no reputation. The artillery horse is the type desired: In general the horses are too light, too fine, and hence the leaning towards the omnibus horse as the ideal, which has endurance, is large, draws well, and trots. There are twenty-two official depôts of stallions in the country yet the amelioration in the breed does not produce the expected results, because no care is taken in the selection of the mares to be covered; farmers simply aim to have a foal. It is suggested that the stallions of the State be allowed, without fee, to serve only those mares selected by competent local authorities; the receipt for the service would serve later as a leaf from a herd-book, for purchasers of the progeny. The Government also could undertake to select private stallions, and to indemnify owners for their services.

An old Alsatian agriculturist, as the results of his experience in the standing dispute as to the milking qualities of the Durhams, states he has only pure Durhams in his sheds, that yield their average 14 quarts of milk daily; that the secret to make Durhams good milkers, is not to "fatten" the stock during the first years of their existence, nor yet insufficiently feed them; for it is during the first year of the animal's growth, that a pound of flesh costs least to produce. Taking food as the base of calculation, he finds no breed pays relatively better for their keep than Durhams, and they consume from a fifth to a fourth less rations than Dutch or Swiss cows.

Leibig was the first to raise his voice against the exhaustion of the soil caused by the cultivation of beet for sugar. He showed that all the alkalies contained in the roots were concentrated in the molasses, hence, the "fatigue," or exhaustion of the soil within a short period. Potash is absolutely necessary in the functions of the plant to produce sugar, and even when returned directly to the soil, it fails to restore the latter's vitality for beet cultivation. This apparent anomaly is due to the fact that the organic matters of the surface soil rapidly seize and retain the salt, while beet, being a tap rooted plant, draws its food from the depths of the soil where the sustenance is limited, and so becomes insufficient after a few crops of beet. This is the explanation of many, why the soil of Saxony and of other regions now fails to produce sugar beet. Soils repel the plant, which about July commences to fade, sinks into decrepitude, and rots—the leaves last. If a vertical section of the root be now made, the tissue will be found covered with red rings, the first indication of decomposition. These roots yield little sugar, and the pulp will not preserve in trenches; even when sound, the sick roots communicate contagion to a whole pit. The soil occasionally displays signs of weariness one season, recovers another, but relapses into more intense fatigue afterwards. In addition to the explanation of exhaustion, Messrs. Liebscher and Marker of Halle, have discovered the presence of a parasite called *nematode*, which is as numerous, and propagates as rapidly, as the phylloxera itself; they are to be encountered on the rootlets in the form of white specks; rarely on a diseased plant, for having destroyed the latter's feeders, they decamp. These insects are never found in large numbers where the beet thrives well; they are more frequent in a soil where the beet is raised for seed; and it is essential never to employ the washings and root-trimmings of the sugar factory, if the beet delivered appears to be affected. It is not clear if the presence of the *nematode* be the cause or the consequence of the disease; it is a diagnosis of the malady, and may resemble the animal economy, where parasites prey on bodies insufficiently nourished.

The relative value of beet pulp is important. The sugar or juice is extracted in two ways; by rasping the root and pressing the pulp, or by cutting the root in thin slices, and steeping them in warm water. The first plan breaks up the cell, and pressure mechanically forces out the contents; the slicing keeps the cells more or less intact, and the warm water exhausts their contents by the law of diffusion. The second method is common in Germany and Austria, and is spreading to Holland and Belgium; but farmers dislike the pulp, as it contains 94 per cent. of water; it is inconvenient for carriage and objectionable for feeding purposes as too aqueous a dietary necessitates a useless expenditure of animal heat to raise the water to the temperature of the economy; further, too diluted food augments the decomposition of the albumen in circulation. However, by employing the Kluseman press the percentage of water can be largely reduced, with not a greater loss than 3 per cent. of dry matter; in this condition it will conserve well in pits, and retain its superiority of richness in albuminous substances. Unpressed, according to Dr. Petermann of Belgium, the slices are commercially only half the value of the rasped pulp; reduced to a like degree of humidity, the sliced is richer than the grated pulp for feeding purposes. M. Barval has analysed some English beet roots, the Mammoth variety, weighing 30lbs. a root; he found them to be so rich in nitrate as to be positively dangerous for alimentary, as they are totally unfit for sugar purposes. Molasses contain a portion of sugar, to separate which many processes have been tried, but all of which, while liberating and securing the five or six per cent. of pure potash, destroyed from 10 to 12 per cent. of potash salts, and two per cent. of nitrogen in the ammoniacal and organic form, during distilation. By the discoveries of Messrs. Scheibler and Seyferth, this combined potash and nitrogen can henceforth be utilised. Sugar being composed of carbon, oxygen, and hydrogen, science and mechanics ought to be able to restore all the other complimentary matters of the beet to the soil, either in pulp, scum, or washings. The beet harvest of 1878 has been better for the cultivator than the manufacturer; active operations are going on for this season's crop, which will be very extensive, as is ever the case after a bad wheat year; such as that just expired. If the farmer employs the seed given him by the factory, the beet will be taken from him at fr. 17, instead of fr. 18 the ton, the density of the juice to mark 5·2. French growers have not been yet able to realise 8 and 10 per cent. of sugar, as is done in Russia, Austria, and Germany.

Many French farmers who purchase lambs to fatten for the butcher, lose about 10 to 20 per cent. of them, when six weeks old, from the "gout"

as arthritis. This is not an uncommon ailment among young cattle and horses in Hungary, Saxony, Prussia, &c.; but for lambs, it is rather new. The disease affects the animal during the first months of their existence, and during the suckling stage only. The cause is attributed to an alteration of the mother's milk, and its deficiency in phosphates or mineral matter. The symptoms of the disease are painfulness in walking, a tendency to lie down, tumefaction of the joints, which are hot and swollen, strong fever, rapid respiration, spasmodic contractions, absence of appetite, ardent thirst, the animal endeavouring to crawl to a trough, or to suckle its mother, constipation at first, followed by diarrhœa, and terminating in dysentry, slight running at the nose, and, after a few days, death. The "remedy" is of little value, one ounce of Glauber's salts. Better see that the soil be supplied with phosphates, and when the gout appears in the sheds, give the ewes an aqueous dietary of carrots, beet, parsnips, &c., putting a little of the aforesaid salts in the drink or sprinkling it over the roots, a linseed drink with a little aloes or bicarbonate of soda thrown in is not bad. In thus treating the mothers, one prescribes for the lambs.

RAINFALL RETURN FOR COLOMBO.

THE ABSORPTIVE POWER OF SOILS.

DR AITKEN'S seventh lecture on the Chemistry of Agriculture delivered in the Highland and Agricultural Society's Hall, was on "The Absorptive Power of Soils."

Dr. Aitken demonstrated the fact that ordinary dry earth has the power of absorbing many kinds of colouring matter from solutions containing them, and that different samples of soils had very various absorptive power. This was shown to be not merely a mechanical filtration, but in most cases rather due to chemical action. The researches of Way, thirty years ago, the lecturer said, added much to our knowledge on that subject. He found that when solutions of certain salts were poured upon soil contained in a pot, the water which drained away had a very different composition—the base of the salt was retained by the soil, and exchanged for a proportionate amount of lime; thus when a weak solution of sulphate of ammonia or sulphate of potash was poured on the soil, the water which passed through contained sulphate of lime, but no ammonia or potash. This was a fact of great importance to agriculture; for experiments showed that the bases most firmly retained by soils were precisely those which plants required most for their nourishment. The soils which absorbed these best were found to be those which had been most completely weathered. The absorption of ammonia by soils had been very carefully investigated by Voelcker. He found that a certain amount of ammonia was absorbed by all soils, and that though water was able to wash out a considerable amount of it, yet it could not take it all; and this was very important information to farmers, as it assured them that ammonia applied to the soil would be retained by it during ordinary seasons, and that even during very wet seasons it could not all be lost. The special constituents of the soil which favoured its absorptive power were only imperfectly known. Silicates of alumina and iron, weakly combined with other bases, were thought by some to be especially favourable. Organic matter, also, was known to have a great power to absorb ammonia; but owing to the exceeding complexity of soils, and the great variety of chemical combinations and decompositions capable of going on in them, it was impossible for chemists to do more than guess at the relative importance of the various constituents of soils, as affecting their absorptive power. The solvent action of the roots of plants still further complicated the inquiry. The state of combination in which plant food existed in the soil was of the utmost importance to its fertility. Liebig advanced the theory that it was only such food as was in physical combination that availed for the nourishment of plants; but such a hypothesis was unnecessary. Substances in highly complex, but weak chemical combination in the soil, were in the best condition for being decomposed and absorbed by the solvent power of the root. What the solvent power of the root is we do not know, and have tried in vain to imitate it. Were we able to imitate the solvent action of the root, we could then determine in the laboratory the precise measure of fertility of various soils. But so far from being able to do this, the chemist is scarcely able, from his analysis of a soil, to say whether it is fertile at all. Soils known to be barren are sometimes found to contain all the elements of plant food in greater abundance than soils that produce large crops. The method of analysis employed by chemists is successive treatment with weak and strong solvents, as water and hydrochloric acid; but these bear little or no resemblance to the action of the root. Soils treated with strong acid have been found still to yield nourishment to plants. H. Von Liebig tried weak acetic acid; Grandeau recommends dilute ammonia; others carbonic acid and water; but all these were merely empirical efforts to gain some kind of indication of fertility, whose success or otherwise depended on the accidental character of the soil. Knop had made a valuable research with the view of discovering a measure of fertility in soils, and was of opinion that the silicates of the sesquioxide formed a good criterion, no soil, he found being fertile which contained less than 3 per cent. of these.

There was one direction in which the chemist was able to give valuable information. He could tell the cause of barrenness when that was due to the want of some important element of plant food. No soil was fertile which had not the elements of plant food; but it might have the elements of plant food and yet be barren, or nearly so.

The lecturer then proceeded to describe the various conditions of the soil most favourable to weathering—the effect of warmth, moisture, and organic matter. The dark colour of a soil favoured its absorption of heat; the lighter the colour the more heat was reflected and the less absorbed. Dark soils, therefore, weathered quicker, and caused the crops to germinate and ripen more rapidly than light-coloured soils; and this was a matter which the farmer had to some extent within his own control; for the application of soot on the one hand, or calcareous shells on the other, tended to darken or lighten the colour of the soil, and so to hasten or retard the ripening of the crop.—*The Country Gentleman's Magazine.*

A REMARKABLE PARASITE.

THE life, history, and the agamic multiplication of the aphididæ have always excited the interest of entomologists, and have even attracted the attention of some of the most eminent of our naturalists. To every amateur gardener—nay, to every grower of a geranium or a rose bush, these destructive pests are known; the now notorious grape-vine phylloxera belongs to the family. With all their vast numbers and their universality, their life history has baffled the skill of many an observer, and this has been especially the case in the gall-making forms which so disfigure our trees. Researches carried on into the life of the phylloxera have, however, somewhat cleared the way, and Dr. Riley begins Vol. 5, for 1879 of the "Bulletin of the United States Geological Survey" with some biological notes, in which he recounts the following most remarkable history:—It will be remembered that destructive as these insects are, they are most fragile, and languish in confinement, so to trace out all their daily history for a space of over ten months was a labour requiring diligence and perseverance—one that probably would not have been successful had not Dr. Riley been helped by an enthusiastic lady friend. The first species studied is known as *Schizoneura Americana.* It infests the leaves of the America elm, sometimes in such numbers as to cause all the leaves to fall. If during the winter the cracks in the bark of an American elm that was badly infested with this leaf-curling species the previous summer be examined there *will pretty surely* be found here and there a small dull yellow-coloured egg about 5mm, long, probably still covered with the remains of the female's body quite dried up. Out from this egg will in the early spring be hatched the little crawling creature which constitutes the first generation in a very remarkable series, settling upon the tender opening leaves. This "stemmother" begins to feed, causing the leaf to swell up and pucker until it at last curls over the tiny form. After three moults and the temperature being warm, it commences to people the leaf with young, at the rate of about one every six or seven hours. The second generation, though they never grow to be at all as large as the stem-mother, are like her in many respects. They accumulate in vast numbers, some of which, scattering, form new colonies. Their issue forms the third generation, which are destined to become winged. These winged forms are short-lived, but they lay 12 or fens pseudova at average intervals of about half an hour. The young

plant-lice from these form the fourth generation, the members of which are very active, running swiftly. They are of a brown colour, and are somewhat like in general appearance of those of the second generation. In this stage they swarm over every portion of the tree, and their necessities cause them to migrate, in which effort masses of them get destroyed. The fifth generation is very similar to the fourth. It gives rise to forms like the fourth, but without wings. These give origin to the sixth generation. All of these acquire wings. These abound in the latter end of June, and early part of July. They congregate on the bark, seeking out sheltered cracks or crevices, in which they deposit their young. These form the seventh generation, and are sluggish, of the colour of the bark, the females a little larger than the males. They have no mouth. They live for several days without motion. The female seems to increase in size by the enlargement of her one single egg. Both sexes soon perish, leaving among their shrivelled bodies the shining, brownish, winter egg, with which we started; so, after a long series of vegetative reproductions, at last the time comes for the renewing of the race by this zygospore-like body. Surely in this lies a hint to our plant growers. It would be easier to destroy a single egg than stop a stream of agamic-produced forms extending to six generations.—*Glasgow Mail.*

THE ELECTRIC LIGHT.

EXPERIMENTS AT THE ORWELL WORKS.

SOME interesting experiments with the electric light were made at the Orwell Works. The success achieved by Messrs. Ransomes, Sims, and Head, with their patent governor for securing regularity in the running of engines for generating electricity has gained them a wide reputation, and they are just now executing an order for four engines and machines combined for the Indian Electric Light Company for use in India. For electric lighting one of the greatest difficulties to contend against was the necessity for regularity in speed, and to secure this Messrs. Ransomes adapted their patent automatic governor expansion gear, which regulates the movement of the engine to such a nicety that the revolutions remain without any perceptible fluctuation. In all the experiments which have been made it was found better to employ separate steam engines, than to use any engine which might be at work in the factory or place requiring to be lighted, and this has induced the Messrs. Ransomes to turn their attention to the adaptation of their portable engines for electric purposes. They have met with success in the undertaking, and have adapted four 6-horse power engines for the Indian Company. The electric apparatus is carried on a platform extending beyond the smoke-box of the engine, so that the whole of the machinery, motive power, and electric generating and distributing, is self-contained, and the engines being portable, they are readily transported from place to place. The Gramme machines are employed, and as there are two to drive—one exciter and one divider and alternator—the engine is fitted with two large fly-wheels, one for each machine. The Jablockoff candles, which are used with the Gramme machines, consist of two points of carbon placed in a parallel position, with a thickness of non-conducting material between. As the positive point always burns more rapidly than the negative, the alternating machine was introduced, so as to throw the current backwards and forwards from point to point several thousand times per minute, and in this manner keep the carbons perfectly level. Each candle is equal to about 600 sperm candles, and six lights can be kept burning by one engine. To produce the light, the exciter machines makes 1,200 revolutions per minute, and the divider 1,100. The arrangement for carrying the electric machines was designed by Messrs. Ransomes, and the plan adopted is simple and effectual. The platform rests upon an arch of iron, firmly fixed to the engine; and to secure perfect tension of the driving strap, the machines are placed upon a sliding table, worked by means of a screw, which enables the man in charge to regulate them to the most exact nicety. This aparatus is constructed from the designs of M. Dolfus, engineer to the Indian Electric Light Company, who personally conducted the experiments. At the trial the painting shop at the Orwell Works was light by six of the Jablockoff candles, and was never lighter during the brightest summer day. The building is 126ft. long by 24ft. wide, and is ordinarily lighted by 18 gas jets from the roof, which it is needless to say were quite eclipsed by the brilliant and steady light produced by the engine. Though six candles were used three would be amply sufficient for lighting such a space. We should add that the engines in question have been constructed with fire boxes of extra large dimension so as to burn every description of wood and the inferior fuel commonly found in the east. This marks a further stride towards the development of the electric light, and we heartily congratulate the Messrs. Ransomes on being the means of affording an additional proof of its utility for illuminating purposes.

INDIAN PLANTS ADAPTED FOR COMMERCIAL PURPOSES.

BY JOHN R. JACKSON, A. L. S.

(Read before the Society of Arts, March 7.)

THE recent adaptation in this country of many products and remedies furnished by Indian plants has directed fresh attention to our Eastern possessions, as a source from whence we may, in time, expect to receive many new and valuable commodities. Considering the vast extent of country, and the varieties of climate that prevail over the great Indian Continent belonging to the British Crown, it is, perhaps, not a little surprising that more has not already been done to develop its resources. It is true that several noble efforts have been made to introduce and acclimatise foreign plants of acknowledged commercial value, and this extending over a number of years down to the present time; and some to these efforts have been eminently successful. It is not necessary for me to do more than merely refer to these introductions, by which you will understand me to allude primarily to the cinchonas, the Para rubber plant, and the mahogany tree. There is, no doubt, a large field still open for successful culture in India of many valuable economic plants, not only those which, like the cinchonas themselves some years back, are in great danger of being exterminated from their native homes, but many also whose wider geographical range of culture would add to the world's resources, and, by competition, produce larger supplies, at consequently cheaper rates to the consumer; and besides this consideration for the consumer at home, the larger the area of land put under profitable cultivation the better it is for the country concerned, not only on the score of increasing its revenues, but, what is of equal importance, the employment of the population in tilling the soil, or in the various arts and manufactures which proceed from a system of high cultivation, and, as a result of all this, a contented and prosperous people. It will not be denied that these are points to be aimed at in the formation of any new country, and, though India cannot be said to be a new country, either historically or in its relation to England, we, unfortunately are not in a position at the present time to say that that peace and prosperity, so desired by us all, reigns over the extent of our Eastern Empire. On the other hand, India still requires much careful consideration, not only from the diplomatist and the military tactician, but also from those skilled in the arts, manufactures, and commerce, on whose individual or united exertions much of its future prosperity depends.

It is not to the subject of the introduction or acclimatisation of foreign plants in India, of which I have incidentally spoken, that I wish to draw particular attention. There is plenty of room in the country for this kind of work to go on, and there are plenty of plants suitable for such introduction; but it must not be forgotten that India is specially rich in plants of acknowledged economic value, whether they be regarded as furnishing food, medicine, or clothing materials; but, over and above this, it possesses numberless plants, the value of which is not known out of their own country, or if known is not yet appreciated and these consequently await a further development of their uses. Then again, going still further, we may say, we shall be disappointed, if absolutely new properties are not discovered in many plants as they become more known, and by their more extended application the money value of the vegetable products of India will go on increasing. Of the extent and variety of these products at present known a good idea may, of course, be had from the fine collection in the India Museum at South Kensington, or from a glance at the extensive series brought together at the Paris Exhibition last year. This most valuable collection, which included woods, fibres, gums, resins, drugs, &c., was got together by the officers of the Forest Department under Dr. Brandis, and though the collection exhibited at Paris has found a resting place in the Forest School at Nancy, I am sure you will be glad to hear that a duplicate set has been sent to this country, and is now deposited in the museum at Kew. This collection is one essentially of forest produce, and, as such, exhibits the great importance of the Forest Department as it is managed in India; for besides the preservation and extension of valuable timber trees, which may be considered the legitimate work of forest conservancy, the production of gums, resins, and not a few drugs is necessarily associated with them. Were the work of the conservancy department confined to the preservation of trees for the sake of their timber alone, this would, indeed, be a good work, for we must not forget how rich India is in woods, valuable both for structural and cabinet purposes. Thus, for instance, next to our own European timber, oak, teak takes foremost rank, and is very widely known and used. The preservation, therefore, of the teak forests, of the sál, sandal, and other similar woods, is a matter of vital importance to the country, and it is satisfactory to know that this branch of Indian produce is now placed on such a sound and practical basis; and though there may be differences of opinion as to the means we have in England, or rather the lack of means, for the training of forest officers for India, we can but feel the necessity of a similar forest department in many other parts of the world. Included amongst forest produce, the bamboos hold a prominent place, whether we consider the endless uses to which they are put in India, or their more extended application to which so much attention has recently been drawn, namely, that for paper making. It would occupy far too much time, besides going over ground that has been traversed before, to give even the heads of the statements put forward in favour of the bamboo, or of those advanced against its practical and profitable utilisation. The opinions of Mr. Thomas Routledge on the one hand, and of Dr. King, superintendent of the Botanic-gardens, Calcutta, on the other, will no doubt be fresh in the memory of many members of the Society of Arts, having recently appeared in your own *Journal*. Those interested in the subject, I would advise, to obtain a little pamphlet recently issued by Mr. Routledge, under the title of "Bamboo and its Treatment," as well as Mr. Routledge's first pamphlet, published in 1875 by E. and F. Spon, entitled "Bamboo considered as a Paper-making Material." Whether the trade in bamboo as a paper-making material will ever develop into an acknowledged branch of commerce remains to be proved; to say the least, it seems not at all improbable, and so satisfied on the subject is Mr. Routledge, whose opinion must be taken as having some weight, on account of his great practical experience, that he says in the preface to his most recent pamphlet:—"Desiring to fully ventilate the question generally of fibrous material suitable for paper-making purposes, I have appended hereto other data bearing on this important subject which merit full consideration, not only

from a practical but commercial point of view, especially in relation to our great Indian dependencies."

In considering the suitability of Indian plants for commercial purposes I cannot hope to introduce to notice anything absolutely new. Indian botany has received the attention of some of the most prominent botanists the world has produced, notably Roxburgh, Wallich, Griffith, Wight, Hooker, and Thomson, and amongst those who have taken up Indian botany specially from a practical or economic point of view may be mentioned Royle, our honoured chairman, Birdwood, M. C. Cooke, and a host of others. The foundation of botanic gardens, and the work that has been carried on in them, together with the formation of agricultural and horticultural societies in different parts of India, have all had their influence for good, by introducing new methods of cultivation, by offering prizes for essays on the cultivation of some well-known economic plants, or for the improvement by cultivation of indigenous fruits and other produce. It cannot be denied that the existence of these societies not only has given and still gives an impetus to cultivation, but spreads a knowledge of the uses of plants among their members, and an interest to further and develop those uses, or to find new applications. Regarding the introduction into, and the distribution from, India of new plants and seeds, which is to a certain extent carried on by the societies referred to, much of course is done by the Government gardens at Calcutta, Saharunpore, Madras, Ootacamund, and Bangalore. All these gardens are centres of botanical knowledge, and are superintended by well-known and competent botanists. That the uses of botanic gardens are thoroughly understood and appreciated in India would seem to be proved from the fact, as we learn from a recent number of *Nature* of its having been proposed to establish Presidency Botanic-gardens, and a committee chosen for considering whether Poona or Bombay should be selected as the place for the principal garden of that Presidency, the decision being in favour of Ganesh Khind. "They recommend, however," continues the paragraph above referred to, "that a small branch garden, consisting of four or five acres, be established in Bombay." "The Government," we are further told, "highly approved of all the recommendations, which will be carried out whenever financial means may permit." The main scientific garden, which will embrace about forty acres, is to be laid out in the irregular picturesque style, with special reference to landscape effect, and the planting of the ground will be done gradually and without any undue haste." The chief resources of the garden, it seems, are to be devoted to the bringing together of the indigenous plants of Western India, and, until this is satisfactorily accomplished, no pains will be taken, except in special cases, to introduce foreign plants. A herbarium, botanical library, and class rooms, furnished with diagrams, are to be attached to this garden. Having said so much about the value of botanical gardens, and agricultural and horticultural societies, in diffusing an interest in plants and their consequent utilisation, I will next briefly allude to what has been done in furtherance of the same object by the aid of books. Many gentlemen here present know as well or better than I do of the extent and value of this class of literature, and I need only mention the titles of a few, such as Royle's "Productive Resources of India," "Fibrous Plants of India," Drury's "Useful Plants of India," Birdwood's "Bombay Products," Balfour's "Timber Trees of India," and last though not least, Brandis's "Forest Flora," to show that Indian products have received from time to time a great deal of careful attention; and, even down to our own day, I might further mention the labours of Dr. Cooke on the gums, resins, oleo resins, and oils, and those of Dr. Dymock on Indian drugs, which have been appearing periodically for the last two years or more in the *Pharmaceutical Journal*, to say nothing of the numerous papers to be found in the *Journal* of this Society. In view of all the illustrious names I have mentioned, besides many others that will occur to you who have quietly, perhaps for the most part with their pen and without any pomp of State, helped to make India what we see her at the present day—in view, I say, of all this, it does seem presumptuous on my part to come before you to ventilate the subject that would have been much better introduced by many gentlemen in this room, who have spent a portion of their lives in India, or, who have made India's products their special study. Of the Indian plants that appear from descriptions of their uses already given, or from the uses to which they are known to be put in their native country, I can only enumerate a comparatively few, sufficient; however, for the purpose of illustrating that the resources of India, let alone those of the world at large, are far from being exhausted. New products in the vegetable kingdom undoubtedly there are yet to be discovered; indeed, scarcely a year passes but some novelty is brought to the knowledge of the authorities at Kew, as the director's annual reports show. Speaking generally, a very great deal more might be done than is done to bring new products into use, or to develop the applications of others of which we at present know but little. Hitherto it has, unfortunately, been the fashion to condemn without a lengthened and fair trial any new product that may have come into the market, unless it bears prominently on the face of it an indication of commercial success. Naturally, the first question is will it pay? and if at the first onset from various causes it appears as if it will not pay, it is cast on one side, perhaps to crop up again at some future time more or less remote. Notices may be written and descriptions given in the various journals of our day, but unless the new product has at first some very strong claims, or some competent and energetic champion comes forward to stand by it, it more frequently sinks into oblivion. No surer or better way to prevent this, and to make the resources of any country known, is to bring the matter before the ordinary or sectional meetings of this Society; where it can be freely discussed, both in its scientific and commercial bearings; and it is with this view that I wish to point out some economic products of Indian origin that have recently been introduced into this country, and have now become recognised articles of trade, in the hope that my simple statement of facts will act as an incentive to further research into the properties of Indian plants known to be used by the natives whether for food, medicine, or manufacture. At this point I cannot but refer to what has been recently done by Mr. Thomas Christy in bringing commercial plants to the light of day, since, by a thorough investigation of all products which appear to be really useful, and introducing them to the commercial world, several have become acknowledged articles of trade between India and this country. I will now direct your attention to a few of these commercial plants from India, the most important of which is undoubtedly the *Gynocardia odorata*, or chaulmugra tree. It belongs to the natural order Bixaceæ, and is a large tree, native of Pegu, Tenasserim, and other parts of the Malayan peninsula, extending into Assam, Khasia, and Sikkim. It does not, however, reach the central or western parts. The fruit is round, somewhat like a large orange, containing numerous irregularly avoid seeds, and it is from these seeds that the oil is expressed: it has a faint unpleasant taste and smell, and, as found in the Indian bazaars, is usually very impure. Mr. Christy says, in a pamphlet recently issued by him that, "the pure oil in India is expensive, and therefore offers a great inducement to the natives to adulterate it; indeed, adulteration is carried on to such an extent, and is so difficult to detect, that it has occasionally caused medical men in India to discontinue its use. In the Mauritius it is said that so high a value is put upon its purity that the seeds are imported from India for the purpose of obtaining the oil free from adulteration. Though this oil has been long used in India and China as a remedy for skin diseases, and other complaints arising from impurity of the blood, it has only quite recently become used in this country, and now it is greatly in request for consumption, rheumatism, leprosy, and such like diseases, being given both internally and externally. It is being used in several of the London and Parisian hospitals, as well as by some of the leading members of the medical profession. Here, then, is an instance of a new commercial product from India, and one that promises to become an important medicine.

Another plant, which is official in the Indian Pharmacopœia, and which has risen to some importance, is the *Carum ajowan*, or as it is perhaps more generally known as the *Ptychotis ajowan*, an umbelliferous plant, the fruits of which are used in India as a carminative. These little fruits somewhat resemble in appearance those of the caraway, to which they are botanically allied. The flavour is, however, quite different, that of the plant under consideration having a thyme-like taste and smell. The commercial importance of these fruits as a source of thymol, a valuable antiseptic, is referred to in the *Pharmaceutical Journal* for the 22nd of February, were we are told that Messrs. Metsner and Otto, of Leipzig, alone sent out, during the months of September and October, more than a ton of this substance. The works of this firm, it is further stated, are occupied day and night in its preparation, and the demand for thymol and thymol wadding is greater than ever. This firm appears to use the fruits of *Carum ajowan* as the source of thymol, but they state that they have advices that not only has the price of the fruits advanced through a bad harvest, but also through the increased consumption of them in India by the natives during the very sickly season of last year. The *Carum ajowan* is an annual harbaceous plant, and, besides occurring wild in many parts of India, Affghanistan, Persia, Egypt, and adjacent countries, is also cultivated in the same districts for the sake of the fruits which are used in the countries just mentioned on account of their carminative and stimulant properties. Still another new drug—new, that is, to this country, but long known in India—is the rusot (*Berberis aristata*) an extract of the bark of which is now being tried in this country, having been used in India in ophthalmic cases and as a febrifuge from a very early period. The official preparation is the watery extract prepared from the root bark. As the article is quite a new one, as far as English practice is concerned, I am unable to give you any medical opinion as to its therapeutic value. *Berberis lycium* and *Berberis asiatica* both yield a similar product. Turning from drugs, our mind is directed to a peculiar product, which a casual observer would, perhaps, take for deteriorated sultana raisins. Upon closer examination, however, these prove to be the flowers of the mahwa tree (*Bassia latifolia*). This tree grows to 40 or 50 ft. high, with a trunk 6 to 7 ft. in girth, and is abundant in all parts of Central India, from Guzerat to Behar. The tree is propagated by self-sown seedlings. The following notes on this tree were read before the Linnean Society last year by Mr. Lockwood, who spent some time in an official capacity in Monghyr. He says:—

"Any one, standing on the dry metamorphic Karapoor hills in the district of Monghyr, 250 miles north-west of Calcutta, and looking into the plains below, may see a hundred thousand mahwa trees, which, if fresh from Calcutta, he will probably mistake for mango trees. But, unlike that of mango trees, which are uncertain in their yield, the mahwa crop never fails; for the part eaten is the succulent corolla, which falls in great profusion from the trees in March and April. This season is a great feasting time for the humbler members of creation. Birds, squirrels, and tree-shrews feast among the branches by day, whilst the poor villagers collect the corollas which fall on the ground on all sides. Nor does the

...ing end with the day. At sunset, peacocks and jungle fowl steal out ... the surrounding jungle to share the mahwa with deer and bears, many of which fall victims to the bullets or arrows of the hunters, who sit concealed in the branches over-head. South of the Ganges, in Monghyr, the mahwa is by far the most abundant tree. It grows on poor stony soil, ill-suited to most other trees or for the plough; and, fully appreciating its valuable properties, the native protect it wherever it grows. During the four years which I passed in Monghyr as magistrate, I visited every part of the 4,000 square miles under my charge in the cold season, paying constant attention to the natural history, particularly to the botany of the district. The mahwa tree, which I had not seen previously in Lower Bengal, attracted my especial attention; and I calculated that there must be not far short of a million trees in Monghyr alone. Each tree yields two or three hundred weight of corollas; so that the total yield of mahwa flowers cannot be far short of a hundred thousand tons in Monghyr alone. Of this amount a vast quantity goes to feed the forest birds and beasts; but of that portion which is collected by the natives by far the greater part is eaten, and supplies nourishing food to the poorer classes. The Santhals, who use it largely, are a plump and happy race, the only people I have ever seen in India who enjoy a hearty laugh, and this I attribute partly to the nourishing qualities of the mahwa, supplemented with venison and other wholesome game which the woods supply.

"During the season of scarcity which prevailed at Behar during 1873-74 the mahwa crop, which was unusually abundant, kept thousands of poor people from starving, and all famine officers will recall its peculiar odour as they passed through the villages where it had been collected. The residue of the mahwa which is not eaten is taken to the distillery, and there, with the aid of rude pot-stills, is converted into a strong-smelling spirit, which bears a strong resemblance to whisky. The Government holds a monopoly of spirit manufacture, and when I first went to Monghyr, in 1873, the custom was to charge a duty of eight shillings for every cwt. of the raw material as it entered the distillery, on the supposition that so much mahwa would only yield three gallons of proof spirit. Subsequently, in consequence of experiments made by the officers under me, this duty was somewhat raised; but in England I find that over six gallons of proof spirit can be produced from a hundred weight of mahwa. The Government of India should be made aware of this fact, and it would probably be advantageous to introduce a patent still in the place of the rude machines now in use. The amount of mahwa which nominally paid Government duty yearly in Monghyr was 1,750 tons; but with patent stills under Government control, the mahwa would probably yield a much larger revenue to the State. An Italian gentleman, who was living at Monghyr, when I was there, took out a patent for removing by a very simple process the essential oil, or whatever it is, which gives the mahwa spirit its peculiar smell; and for some time I thought he would make a rapid fortune; orders poured in on him from Calcutta, and the demand promised to be immense. But just as the inventor had taken up a whole side of the Government distillery, and got all his preparations complete, the rum distillers in Calcutta petitioned the Board of Revenue, and a prohibitive duty was imposed, which completely put an end to the manufacture of scentless mahwa spirit. A sample was sent to the chemical examiner at Calcutta, and he reported that the spirit was pure and wholesome, and came very near good foreign spirit."

Besides the uses here referred to, mahwa flowers are stated to be still more useful for feeding cattle. Pigs have been fed upon them in this country, and the flesh pronounced excellent. One great point in connection with these flowers, as a commercial article, is that the crops are never known to fail. Mr. Lockwood further says that the oldest inhabitant in Monghyr had never heard of a season when the mahwa crop was not abundant, for the flowers are always produced in great quantity, whether the fruits afterwards ripen or not. The extraordinary keeping quality of the mahwa is also another recommendation to its introduction into England. Before leaving India, Mr. Lockwood had a ton of these flowers shovelled into sacks and put on board a vessel at Calcutta. They were gathered in April, 1876, and after being kept for nearly two years were as good as when first dried. Mr. Lockwood thinks India would benefit greatly if mahwa flowers met with a demand in England. The vast forests of mahwa trees, which now yield little profit to their owners, would soon become a source of wealth, and the collection of the corollas would give work to thousands of poor people who at present inhabit the rocky country where the mahwa grows. The merits of these flowers for distilling purposes and for feeding cattle seem to be—1, cheapness; 2, unlimited supply; 3, certain yield; 4, nourishing qualities; and 5, good keeping qualities. Besides these uses to which the flowers of *Bassia latifolia* have been suggested for adoption in this country, the oil obtained from the seeds has also received some attention. It is used to adulterate ghee, or clarified butter, and Dr. Cooke, in his report on "oil seeds and oils in the India Museum," says the oil was long since submitted to Price's Patent Candle Company, and its applicability for candle manufacture ascertained. The report states that it is worth in this country, for the manufacture of candles, £5 per ton less than Petersburg tallow. A great many experiments had been tried with it, and it was found to be of the same value as cocoanut oil, as its being harder compensated for the colour being inferior. Large quantities, it was said, could be used in this country at about £35 per ton. This statement was made two years ago, and the value of the oil may have changed since then. That India is extremely rich in oil seeds, a glance through Dr. Cooke's report will show. Apparently there is a wide field here for commercial enterprise. In referring to this subject, a paragraph in Mr. Simmonds' *Journal of Applied Science* goes, I think, quite to the point. We are there reminded that the exports of oil seeds from India are becoming very important, and that India now exports oil seeds to the value of five and a half millions sterling a year, instead of making oil of them there and using the refuse for manure and cattle food, to say nothing about the extra cost of freight. Some vegetable oils are of course exported from India, such, for instance, as castor oil from Calcutta, and gingelly oil from Madras. But European capitalists are wanted to establish oil mills in India, and give their names as a warrant for standard qualities, and then India might hope to make oil one of the chief articles of export. Clever enterprise would soon be amply repaid. There are of course some oil mills in the country, but very few, and in these the oil is by no means made so cheaply as to leave no room for competition. The loss sustained by the country from the exportation of the seeds themselves is simply enormous. In one year four million cwts. of material for oil-cake is sent away, while the cattle are dying of hunger. I give you this for consideration, in the hope that, if the facts are not to be controverted, some steps to remedy such a loss to India may be taken.

It is extremely difficult to particularise any plants specially suited for investigation, as likely to prove commercially valuable; the difficulty is not to find them, where there are so many to select from, but to know which to take first. One man, however, might be specially interested in food products, another in drugs, another in timber, and so on. To the first I would say,—Are there no Indian fruits that we know little or nothing of at present in this country, that could be sent here, if not in their fresh state, preserved in syrup, or candied with sugar? I may instance, perhaps, a few. The guava, for example, is not so well known with us as I think it might be. Guava jelly and preserved guavas we do occasionally see, but they surely might be brought in larger quantities, and sold at a price to bring them into more general use. Then again the rose apple (*Eugenia jambos*), and the fruits of *Eugenia malaccensis*, are quite worth consideration. I have quite recently had an opportunity of tasting candied rose apples from Jamaica, the tree having been introduced into the West Indian Islands, and I can speak highly of their quality, the rose flavour being preserved sufficiently to give them a grateful taste. I am informed by Mr. Robert Thomson, sometime superintendent of the Botanic-gardens, Jamaica, that these fruits are produced in very great abundance, and could be sent into this country in any quantity; steps indeed are being taken to introduce them to commerce. Of course there is the difference of distance between this country and the West and East Indies, and the consequent greater length of time occupied in transit, and increased expenses of carriage, but if other products can be brought from the East into this country, and sold at a low rate, and yet prove remunerative, I do not doubt that these fruits might also become articles of trade. The loquat or, as it is sometimes called, the Japanese medlar (*Eriobotrya Japonica*), though a native of China and Japan, is largely cultivated in many parts of India. The fruits, which are oval, about the size of a plum or small apple, have a sharp, and sub-acid flavour, and are used as a table fruit as well as for preserving; this fruit might perhaps be found worth introducing preserved either in sugar or syrup. I will only just refer to the names of the blimbing (*Averrhoa bilimbi*) and the carambola (*Averrhoa carambola*), fruits well known in India by cultivation, and valued for their acid flavour, to show that amongst fruits alone there is a wide field for experiment; and, as a further illustration of how unlikely things are utilised, I may mention that in the Java collection of the Paris Exhibition last year, some peculiar looking fruits attracted my attention, which, upon closer examination, I found to be those of the nutmeg, the fleshy pericarp of which had been scolloped or ornamentally cut and rolled back, the whole being preserved in syrup, and forming a very agreeable-looking sweetmeat. Another apparently unlikely fruit to be of any service out of India, where, in Cashmere, we know it is used, is the singhara nut (*Trapa bispinosa*) the fruit of an aquatic plant closely allied to the water chestnut of the French (*Trapa natans*). The extended cultivation, however, of this plant has recently been proposed in India, and it is even been suggested that the fruits might be sent to this country. I need not dwell on this point, since it has been fully described at pages 174 and 175 of the *Journal of this Society* for January 31st last. In the matter of drugs, the medicinal plants of India are so multitudinous that it is utterly impossible to point out more than two or three by way of example. Professor Bentley and Dr. Trimen's work on "Medicinal Plants," has, no doubt, been the means of drawing attention to many plants which, though official in the Pharmacopœia of India, are still unknown so far as medical practice is concerned. Thus, a common leguminous tree, known as *Butea frondosa*, yields a resin known as Butea or Bengal kino, which exudes from the trunks of the trees either spontaneously or by incisions; this kino is an official remedy in India, being used in the same way as the ordinary kino of commerce. Other species of *Butea* help to furnish this kino, which is not altogether unknown in this country, being occasionally used as a tanning and dyeing agent. The seeds of the *Butea frondosa* have a considerable reputation in India amongst the Mahommedan doctors as a febrifuge; their use, however, is said to be sometimes attended with ill effects, hence further observations on their action is desirable. The oil obtained from the seeds is used as an anthelmintic. Some further researches in England on the products of this tree might lead to advantageous results. Another important medicinal plant included in the Indian but not in the British Pharmacopœia is the *Dipterocarpus turbinatus*, a large tree found in the forests of Eastern India from Chittagong and Pegu to Singapore. By incisions made in the trunk,

and by the application of heat, a balsamic exudation flows. The average produce of the best trees during the season is said to be sometimes as much as 40 gallons. This oil, or oleo-resin, is known as gurjun, or wood oil, and is described as being an effectual diuretic, suitable for use as a substitute, or in place of, copaiba balsam. It is not impossible that ere long we may hear something more of this oil in our hospitals.

In the matter of new woods, whether for building or cabinet purposes, time will not allow me to enter. It is a question, moreover, that may safely be left to the forest conservators. Suffice it to say that the first consignment of Indian timbers for commercial purposes arrived in this country not many months since, some of which were favourably received. In view of the scarcity of boxwood from the Caucasus, the possibility of India coming to the rescue is a fact to be thankful for.

With these few suggestions, which might have been extended *ad infinitum*, I will draw my remarks to a close, hoping that my poor attempts to draw attention to Indian plants adapted for commercial purposes may not have been uninteresting, and, moreover, may lead to some further development of India's resources.

DISCUSSION.

Mr. Christy thought the Society was much indebted to Mr. Jackson for his remarks. He mentioned the chalmugra seed as having been known for many years; and from information he had received, and papers that his cousin, the late Mr. Daniel Hanbury, had published, it appeared that it was known for many centuries in China, being always brought from India. It was very rare to find it in a pure state, one reason being the great expense, and the Chinese almost always adulterated it. He had had immense difficulty in introducing this oil here. He was on the committee of St. Peter's Hospital, and having this oil here, and having used it for one of his children with marked success, he placed it on the committee table for the surgeons, and begged them to use it. They thought the smell would be objectionable. Having waited a month, and nothing being done, he attended the surgeons and stood by them when they were seeing their out-patients. Knowing them intimately, he suggested—Is not this a case for gynocardia? They said, certainly. In a few minutes another case came forward, and he suggested it should be tried in that also, and as the man was asked to come again in a week he took care to be present. The surgeon was very much surprised by the result, and in the second week the man was nearly well. The surgeon said, "Be sure you come next week," and on the next occasion he seemed quite cured. These were cases of skin disease and syphilis, and were most trying. The surgeon then said there was really something in this oil, and he took it into regular use, and the result was most satisfactory, and he hoped there would soon be a report upon it. He had also sent it to Mr. Treves, at Margate, who had a great many cases of scrofula, and he had also tried it with marked success. He merely mentioned this to confirm the remark of Mr. Jackson, showing the difficulty there was in getting anything new tried. A gentleman in a Government office, knowing he was working at these new things, asked him if he could tell him of anything which would cure his brother, who was suffering from rheumatism and was almost stiff with it, and who had been getting worse for 25 years, the only relief he could get being from chloral. He told him he could not take any responsibility, but if he liked to try some of the oil he would give him some. The brother took five capsules each containing five drops of the gynocardia oil, and on the sixth day he dressed himself and went out, and he had been well ever since. He now carried about a bottle of the oil with him. That showed what might be done if people would only work with these things. The Chinese had been working with this oil for 500 years. The week before last, he was in Paris, and was asked to meet some of the surgeons there. They said it was a very singular oil, and that it sometimes produced indigestion. He said he knew it did, but it was quite safe, as far as he knew, if taken on a full stomach. He was sure, if this was worked at in our hospitals, there would be an enormous demand for this oil. Thymol was also a very valuable drug. Tamarisk galls, again, were entirely unknown in England. It was known, since Ramspecker discovered an apparatus for testing the exact value of tanning materials, that galls only assisted the tanner by opening the pores of the skin, to allow tanning substances to enter; but it was formerly believed that the galls themselves assisted the tanning operation. Now, these tamarisk galls had been brought over many times, but very few tanners knew anything about it; it collected in the docks, and was sold at the rummage sales. Tanners were very anxious to get it in quantities. *Balsamocarpon* was now growing in India; he had sent some seed to India and Australia, and it was the richest tanning substance in the world, containing 90 per cent. of pure tannin. He also showed a specimen of russot. This was being used by some of our oculists, it had been used for a long time in India, but no report had been issued upon it. The mahwa he had also worked at. He had had some of the fruit in a sack since 1876, and there was no change in it whatever. The fleshy corrolla fell from the trees as had been described, and it was eaten with avidity by all kinds of animals, even the carnivora. Some was taken to the Zoological gardens, and there was hardly an animal or bird there but ate it readily. He sent some to Paris, where there are so many professors that they were always anxious for something new. They tested it for spirit, and their report was that it contained the very highest class of spirit they had had submitted to them and yielded a larger percentage than any fruit hitherto tested, and they could hardly believe that it was a flower. It was very singular that this fruit could be landed in England from India at 6s. a cwt., and if six gallons of proof spirit could be made from the cwt., it would be very profitable. It had been offered to the distillers, and they said they should be glad to give £8 to £9 a ton for it. He had written to India for 20 or 30 tons, and though there were difficulties about the transport, he hoped it would soon be sent over.

Mr. Hale said he believed that England, with the produce of India, might be independent of all the world; and he thought representations ought to be made to the Indian Government to try these products, and send over larger quantities, so that the resources of the country might be developed.

Mr. Holmes agreed that it would be wise if the products of India were examined there instead of at home, and some of them sent over here for commercial purposes. One reason why products were neglected was because many of the things sent over were of very little value; another reason was that they were not sent over in sufficient quantities. If Government were to send over some of the products which were considered most valuable by the ton, and put them into the hands of thorough men of business, many of them would speedily be introduced. At present they simply figured in museums, and there were no opportunities for commercial men to test them. He was especially interested in drugs, and on them Mr. Jackson's remarks were very valuable. Indian aconite, especially the Nepaul, when it could be obtained, was eagerly bought up for the manufacture of the alkaloid, because the active in Indian aconite was more powerful than the German. If it could be sent over at a paying price, it would be sold in large quantities. The opium used in this country did not come from India, and it was difficult to find a specimen in this market. It all came from Smyrna, Persia, and Egypt. Now India was a great opium-producing country, and he saw no reason why, if prepared of good quality, it should not be largely used; it only required more care in the preparation. Thymol was another instance of what might be done by a little business energy. It was a powerful antiseptic, and derived its name from occurring in the common thyme; it was now coming largely into use, being safer and less irritating than carbolic acid. With regard to russot, as a rule the extract was rather impure, and appeared to be used from the earliest times, in India, as an application to inflamed eyes. It probably owed its good properties to ferberine, which was also found in India. Dr. Dymock had lately sent him over some mangosteen fruit, unripe, preserved in syrup; the flavour was very pleasant, and it occurred to him that if it were once tasted, it would be much inquired for. Mr Jackson also alluded to the gingelly balsam, which had been brought into notice as a substitute for copaiba. In leprosy it certainly did not answer as well as chalmugra oil, but it was very cheap, and it would no doubt find numerous applications in the arts if not in medicine. He could quite confirm what Mr. Jackson had said about the chalmugra oil. He had lately read a letter from a chemist in the Mauritius, who said it was impossible to obtain pure oil from India, and that he always sent for the seeds. He found the oil obtained by boiling the seeds was stronger than that obtained by cold expression.

Mr. Routledge said he, unfortunately, had no samples of bamboo with him, or he should have been pleased to show them. The subject was of immense importance to paper makers, who at present were almost entirely dependent on foreign counties for their main raw material, *viz.*, esparto grass. He was sorry to say that this material was being more rapidly exhausted than he had deemed possible; only a few days ago he had samples of Spanish grass submitted to him, some of which was not more than 4 in. long. The fact was, it was overpulled, the roots were laid bare, and the winter rains washed away the soil, so that the root stools became impoverished, and in many districts the plant had almost vanished, where hundreds and thousands of tons grew formerly. The largest supply now came from Africa and Algeria, and there it was going through the same process of exhaustion from the same causes. It was therefore necessary, if the manufacture of paper were to continue, that some new material should be discovered; for makers were now reduced to using things such as ground wood pulp, china clay, and other matters which never ought to be put into paper. Some of the cheap papers almost fall to pieces in your fingers. For sometime past he had been turning his attention to bamboo, believing, from investigation, that it would prove the best and cheapest material which could be used, and possessing also the enormous advantage of being produced in illimitable quantities in India. The Chairman would bear him out that three-fourths of the country produced bamboos; in fact, it grew almost anywhere where there was moisture. There had been a controversy going on for some time between him and Dr. King, curator of the Botanical gardens at Calcutta, as to the cultivation of this plant in India, the latter maintaining that it could not be grown or cropped. He believed it could, and he had proved that it would make most excellent paper. The pamphlet Mr. Jackson referred to was printed on paper made from bamboo, and better paper he did not want to see. Dr. Winthrop, the Commissioner of Forests in Burmah, was collecting bamboos for him, and he wrote him that they could be landed at Rangoon and floated down at a cost of Rs. 15 per 1,000, weighing from six to eight pounds. When dried they lost about 60 to 70 per cent. of moisture; so that practically, a ton of dry raw fibre would cost 8's., and that would produce a ton of paper. The bamboo gave the greatest yield of any material he was acquainted with, except perhaps one, the paper mulberry tree. All fibres have to be submitted to a boiling process, during which they lost a large quantity of extractive matter, varying from 40 up to 60 per cent. of the weight of the plant. The bamboo only lost 40 per cent., whilst esparto was supposed to lose 56, but in practice, it was about 46. The test of a fibre as regarded its commercial value was, first, what quality of paper it would make, and next what it would cost to produce the paper. Th

longest price of esparto at present was £6 a ton for the raw material, or allowing for a loss of 50 per cent., £12 a ton. The bamboos could be floated down at cost of Rs. 15 (30s.) for 2 tons of dry material. The unfortunate part of the matter was, that India was such a long way off, and bamboo was very light and bulky. It also contained a large quantity of moisture, so that, if crushed, it had a tendency to ferment and rot. For these reasons he believed that, to make it pay commercially, it must be treated on the spot, and sent over in the condition of what was called stock. The point at issue was whether it could be grown and cropped. By the last mail from Demerara he received two letters, one stating that for three years the writer had cut down whole bamboos, and he did not see any depreciation in the succeeding growth. In the other letter the writer said he had seen bamboos flowering on his estate, and they remained healthy afterwards. The theory in India was, that when a bamboo flowered, it died. There were very many varieties of the plant—probably about 120—and the majority were supposed to attain maturity in about 40 or 50 years, when they flowered and died; but in the West Indies that did not seem to be the case. This gentleman said he had them cut down and burned, and, in a few months, they were as flourishing as ever. He had several other letters to the same effect. The one thing the bamboo seemed to want was a damp, moist climate; it was useless to attempt its cultivation where these conditions were wanting, but in Burmah, where the rainfall ranged from 120 in. to 160 in. all up the west coast, it flourished in great abundance. He had letters from the Assistant-Conservator of Forests there, who had travelled over ther whole country, right up beyond Pegu, and he said that the natives cut it about anyhow they liked, and the more they cut it the better it seemed to grow. He believed the safest plan would be to cut a certain portion of each clump every year—the young shoots; but if a plantation were made, as was done with sugar, rice, jute, and other things, it would minimise the cost of collection and carriage, and it could then be irrigated if necessary. If so grown, he believed you could get enough bamboo for 20 tons of paper per acre. We should then be independent of France, Spain, and Africa and he feared the French Government might before long, impose a duty upon esparto, seeing it was an article of such prime necessity. It was an absolute necessity in these days that we should have paper, and he wondered that this question had been allowed to lag so much. For his part, however, he did not intend to relax his exertions until he had brought them to a successful issue.

Sir Joseph Fayrer said Dr. King was a most eminent practical botanist and if he said the bamboo would not grew in Southern India, it was difficult to question it, but he certainly accepted the statement with the greatest diffidence. He believed if the bamboo would grow anywhere, it would grow in Bengal, and in Burmah. He could not conceive how any one who had lived and travelled in India as he had done, and seen the magnificent clumps of bamboo, even in and about Calcutta itself, could maintain that it would not grow. By judicious cultivation, he had no doubt it could be cropped regularly. He had no idea that it had such a great commercial value, and it seemed to him a thousand pities that it should be neglected; and he hoped what Mr. Routledge had said would be acted upon. He might also allude to the kindred subject of arboriculture. The mahogany tree, although an exotic, grew freely in India, and some splendid trees which were blown in the Calcutta-gardens by the last cyclone, were sold for cabinet making, at prices equal to that of the best timber from Honduras. He had often wondered why the roads in Bengal should not be lined with it; it formed a magnificent shade, and the wood was very valuable. Dr. King was a most excellent and energetic curator, and he felt great difficulty in suggesting anything which might appear in any way to controvert the opinion he had given, but he could not help thinking there must be some mistake about it. He regretted the paper was not longer, but it was quite sufficient to indicate the direction in which search was to be desired. It was very desirable, however, that many of these things should be more used in India itself. India was indebted to England for many products which she could produce as well herself. The impetus had already been given, and many things were now sent over here which a short time ago were quite unknown. The chalmugra oil was well-known to him, and it was a most valuable medicine.

Mr. Francis Cobb said that many present probably were not aware of the obligations they were under to Mr. Routledge for his experiments, and the perseverance with which he had followed up the question of bamboo for paper-making. His idea was to bring the bamboo to a certain stage in India as shown by a small specimen which he would hand to the Chairman. This was not the first time Mr. Routledge had told them about the bamboo, and he was surprised that it had not been taken up to a larger extent. Bamboos were constantly brought here in the shape of dunnage, but they arrived in such a condition as not to be so fit for the purpose of paper-making as if it could be brought in the condition he had shown. The outside was hard, flinty, and unmanageable. But it was evidently erroneous to suppose that the bamboo could not be utilised and become a valuable export from India, as was shown by the practice of the Chinese. They cut off the young shoots and ate them, and split up the young bamboos and made use of them in all sorts of ways. On the other hand they let some grow so large that they made buckets of them. If the Chinese could treat them in this way and still have a constant supply, he could not see why it should not be done in India, especially if they were grown in plantations. Mr. Jackson regretted that oil seeds were exported instead of expressing the oil in India, but it appeared to him that the oil could be much better expressed in England, and the profit arising from the process was in the form of a bye-product—the cake, for which there was a good market. He doubted if anything like could be found for it in India, where they did not fatten bullocks for eating. The price of the cake here was about £2 a ton, and he did not think anything like that could be obtained in India. The bamboo, however, opened a prospect which there was no seeing the end of.* The greater the quantity supplied, the greater would be the consumption, especially as esparto was failing, and in a few years would be at such a value that it would be no longer available for paper-making. If there was a country in the world where opium was raised, it was India, and probably Mr. Holmes was referring to laudanum; but he believed that where Turkey opium could not be obtained, the Indian had been used for making the tincture. So long as the medical man knew what he had, the Indian was as good as the Turkish, and it was merely a question of the rules of the British Pharmacopœia as to what should be called laudanum. No mention had been made of rhea grass, which, if cultivated in India, would form a very valuable export. It was known here chiefly as China grass, but it might be cultivated largely in India. There were also what was called vegetable, silk or wild silks which were worthy of more attention.

Mr. Routledge said the first experiment he made with bamboo, some five or six years ago, on the ripe, matured plant, but it did not answer well. The young bamboo sprang from the seed of the old plant, and it took about 15 years before it became silicious. No matter what species it might be, it went on maturing for a series of years, and being an entogenous plant, it grew until the inside got filled up and it could grow no longer. It could then no longer transmit the sap, its pores, or vessels, became ossified, like the veins of an old man, and it died, having first seeded. The bamboos which came here as dunnage were cut indiscriminately from the clumps, irrespective of age, and in the older ones the exterior portions had got so indurated with silica, that it took an enormous quantity of caustic soda and high pressure boiling to make it manageable. It was then no longer a fibre, but a pulp, which was difficult to dry, and would only produce inferior paper. If they wanted to make paper from wood they need not fetch bamboo from India, because they could get it much cheaper nearer home. After making these experiments on the old matured wood, and finding the difficulties he had to contend with, he was induced to try what he could do with the young plant, and he found, much to his gratification, that very much like esparto grass when the plant was cut with the sap ascending, the young shoots, which ran up 50 or 60 feet high, it could be reduced by gentle boiling into the consistency of cheese, and might be treated with the same felicity as esparto; in fact, it was just like cooking a ripe cabbage, or asparagus. In fact, in the Malaccas, and Maluccas, the young shoots of some species were used for food, and were frequently put in pickles and chutnees.

Mr. Bowden said he should be happy to place five acres of ground, in the Godavery district, under irrigation, at the disposal of any one who would like to experiment on bamboo cultivation free of rent. There were cheap means of transit from there to the port of Coconada.

Mr Geo. Hogarth asked if rhea, one of the most beautiful fibres, was produced in India. He was sorry to say that it was losing ground, the entire responsibility of which lay with those who produced it and prepared it for the market. It was so carelessly put together, that the great bulk of it was useless for anything but paper-making, simply because it was all twisted and gnarled, and there was no possibility of getting it straight. When properly garnered, there was nothing to equal it except silk, and it was being manufactured into every thing a lady could adorn herself with, but, as he had said, it was losing ground from the bad state in which it came over. The price ranged from £5 to £ 80 a ton, which showed what a margin there was to pay for careful preparation. He understood that hitherto it had been retted entirely by hand, which was very expensive, though labour was cheap. The Indian Government had offered prizes for machinery to do it, but hitherto nothing satisfactory had been devised.

The Chairman said the rhea which came from India was often badly prepared, but the China grass was beautifully prepared, and could be obtained in any quantity.

Mr. Hogarth said all he had seen was the common China grass. He understood that a great deal of the difficulty lay in the gathering; if it was not ripened sufficiently in the sun after cutting, there was a deal of acid left in it, which made it snarl in the process of manufacture, and prevented it taking the dye.

Surgeon-General Balfour thought a good deal might be made of the various products of India. Bamboos were grown in enormous quantity on the west coast, they were never shipped, on account of their great bulk, but were made up in rafts and lashed to the sides of the coasting vessels. The great question with all Indian products was—would they pay? and he believed that most of those which would do so were already brought to Europe. The natives were well alive to their own interests, and are not much disposed to make experiments unless they could see their way to a profit. He doubted if it would be possible to obtain a large quantity of chalmugra oil, but there was no doubt of its value. He believed it was the oil which the late Dr. Bhau Dajee used in the cure of leprosy, but both he and his brother kept it a secret. There was a great difficulty in getting it pure. Nearly all the eminent medical men who had written on India and its products had drawn attention to the various commercial products, but it did not seem to produce much effect. There was abundance of opium in India, and he did not know why it did not come to England, but he believed that some of the active properties were more abundant in the

Turkish opium than in that of Bengal. The great difficulty with many articles was their great bulk, nevertheless enormous quantities of jute were now brought here, and quite a large industry had grown up in Dundee and elsewhere in its manufacture. One great difficulty in exporting oils was in obtaining the barrels to put it in. At one time a considerable trade was done in solidifying castor oil, by a process invented by Mr. Loarer, so that it could be sent home in blocks. That lasted for a few years, but it did not seem to have been continued.

Mr. Christy wished to utter a word of warning to Indian exporters. He had learned that week that it was with the greatest difficulty that manufacturers could now use Indian shellac, owing to the quantity of resin and other adulterations which were mixed with it. The people of India had been down on the English manufacturers for charging their cotton cloths, but we could certainly retaliate on them for charging their shellac with resin. With regard to the expression of oil and the use of the cake, he might mention that the Chinese found it pay very well to use the cake, direct on the land for manure.

Mr. Cobb suggested that this was not oil cake but pea cake.

Mr. Christy said that was so. Mr. Routledge's views about cropping the bamboo were quite correct. In China they kept regular plantations which were constantly cropped, and descended from father to son ; a certain quantity was cut out of each clump every year.

Mr. Holmes added, with regard to opium, that the best authorities on the subject said that the better qualities were not prepared in sufficient quantity to export to England. It was the Patna opium which was chiefly used in the hospitals. Some said it contained more narcotine and less morphia than that from Asia Minor. The fact of its not appearing in the Pharmacopœia would not stand in its way if it were equally valuable, because the Persian opium, which was not named either, was largely used by the makers of morphia when Smyrna opium was dear. The Indian opium, he believed, was prepared in a different way, being brought home and stirred up into a paste, whereas the Smyrna was made directly from the capsules ; and probably this affected the quality.

Mr. Cobb thought the true reason why Indian opium was not used was, that the percentage of morphine in it was uncertain ; so that, when you gave a patient 30 drops of laudanum, you might really be giving him the equivalent of 45. Hitherto, also, the Turkish opium had been landed in England rather cheaper than the Indian.

The Chairman proposed a vote of thanks to Mr. Jackson. All the products he had mentioned had a future, and probably a considerable future, before them ; but he would call attention to another product which had not been mentioned, for which we paid on an average upwards of 30 millions sterling per annum, *viz.*, wheat. He had placed on the table a number of samples of Indian wheat, which represented 1,100 or 1,200 specimens sent from all parts of India. The samples came from some 60 districts, and they were equal, and even superior, to the finest wheats which came into the English market. The average price of English wheat at the present time was about 39*s.* a quarter, but that of the samples referred to went as high as 47*s.*, and some of them weighed 65lbs. to the bushel. It might not be known to all, but India was, next to the United States, the largest wheat-producing country in the world, the annual crop being about 30 million quarters, 10 to 11 millions in the Punjaub—about as much as the whole production of England—10 millions more in the North-West Provinces and Oude, and the remainder in other districts. The average production in America was about 38 to 40 million quarters. There had been a remarkably good crop last year, and this together with the universal commercial depression and want of confidence, which prevented importers holding large stocks, was one cause of prices being so low, lower he believed than they had been during the present century. He believed there was a great future for the Indian wheat trade. The year before last we imported upwards of a million quarters ; this year the supply had fallen off on account of the demand in India itself, but by the opening of the Scinde Railway he thought they might look to the day when the Punjaub alone would be able to send us a very considerable quantity, for it produced more wheat per head of population than any other part of India. When the Indus Valley Railway was opened, especially when the bridge over the Indus was completed, the reduction in the cost of carriage, as compared with going to Calcutta, would be equal to about 8*s.* a quarter, enough to make all the difference between a paying and a non-paying trade. Prices at present were exceptionally low, but were not likely to remain so, and with a slight rise he thought there would be every possibility of obtaining large supplies from India at a profit. This was a matter of extreme importance both to England and India, and might have an important influence on the silver difficulty with which we have to contend at the present time. The finest wheats at the Paris Exhibition were not superior to some of these from India.

The resolution having been passed, Mr. Jackson, in acknowleding the compliment, said Mr. Christy had fully borne out what he said as to the prejudice against new products. With regard to Indian opium, the greater part of it was sent to China, where it was illegal to produce it ; but still a good deal was made, and he believed the Chinese Government were contemplating allowing it. He must apologise to Mr. Routledge for not having asked him to bring some specimens of bamboo, but the subject had entirely slipped his memory. He had referred to the *Brucinicia paperifera*, which was a remarkably good paper-making material, and was well known in Japan. There were two species form which they made nearly all their paper. By treating it with oil, they made it transparent, and used it for glass : and, by putting several layers together, they formed a material similar to leather, which they used for book-binding and other purposes. The utilisation of rhea fibre in this country was another illustration of how difficult it was to introduce new substances. About 25 or 30 years ago, this fibre was brought prominently under notice by the late Sir William Hooker, and it was sent to several British colonies, but nothing more was heard of it until 10 or 15 years ago, when it cropped up again in a most remarkable way. The American Consul at Bradford had sent a report to his Government, drawing attention to this fibre, and pointing out that it might be introduced into some parts of the States. This report fell into the hands of the British Government and was sent to Kew, with a request that the plant should be introduced there, and asking whether it was suitable for introduction into any of the British colonies, exactly what had been done long before. It was then again introduced into the West Indies and other colonies ; but it again died out. The Indian Government had offered a large premium for a machine for clearing this fibre in India, because as he understood the great difficulty in the manufacture was the large quantity of gum contained in the bark, which rendered it necessary that it should be cleaned and prepared in the green state. For this purpose plants were grown in the South of France, so that, they might be experimented upon. It was a hardy plant, and grew very well there. Some of the specimens in the Kew Museum were extremely fine, and he saw no reason why it should not be largely grown. Why it was not brought into more use was one of the mysteries which seemed inexplicable.

In connection with the above the following corrections which have subsequently appeared, deserve the attention of the reader.

In the discussion which took place after Mr. Jackson's interesting paper on the above subject on Friday, March 7th, some slight inaccuracies occur in the report of my remarks, which I beg space to correct.

The Conservator (not Commissioner) of Forests in British Burma, who is kindly collecting young bamboo stems for me, and floating them down to Rangoon for crushing, to come to our works here for extended experiments, is Dr. Berthold Ribbenthrop, and to this gentleman I am indebted for much very valuable information as to the habit, cropping, and cultivation of bamboo under irrigation.

One thousand young seasons shoots will weigh from six to eight ton (not pounds), which, losing from 60 to 70 per cent. in drying, and allowing amply for waste, will yield, when converted into stock, sufficient to make one ton paper. These young stems will cost about Rs. 15, say 30*s.* per 1,000 delivered by rafts at Rangoon.

My two informants from Demerara tell me they have cut down entire clumps of bamboo during successive seasons without apparently deteriorating the growth, and one states that even burning the clumps down to the ground has not prevented successive growth, adding that he had seen bamboos seeding on his estate and remaining in healthy growth afterwards, but then it must be noted Demerara is a moist climate and soils suited to the habit of growth of the bamboo.

In a few succeeding remarks, I intended to show that in treating the old and matured bamboo stems I had not succeeded well, inasmuch as they had become wood, and very hard siliceous, or silicified wood, too—and that similarly to other woods they could only be reduced into a pulp by boiling under high pressure with very costly doses of caustic soda—but that when subsequently experimenting on the young shoots in the vegetable or growing stage, with the sap freely circulating, and before silicate and other compounds had become deposited and indurated, I found that, with the gentler boiling and reduced chemicals, I could treat the stems as readily as esparto grass, indeed, just like cooking a ripe cabbage or asparagus in its succulent stage, reducing them into long and strong fibre.

The question, in fact, of making paper—and good paper, too—from bamboo, is settled. The other question to be determined (by the botanists) remains, *viz.*, whether the bamboo can be continuously cropped every season to allow the young shoots to be utilised ; and, speaking for myself, I have not a vestige of a doubt that, if this operation is judiciously conducted, success will result and thus a valuable commercial product be added to the exports of India, while assisting our English paper trade, which sadly needs an extended supply of suitable raw material.

THOS. ROUTLEDGE.

Claxheugh, 17th March, 1879.

In the course of the discussion following the paper on "Indian Plant, Adapted for Commercial Purposes," by Mr. J. R. Jackson, Mr. T. Christy is reported to have said that he found great difficulty in inducing medical men at a certain hospital to try chalmoogra oil. This is so very different from our own experience, that we think the members of the Society of Arts will be sufficiently interested in it to warrant us in begging that you will kindly insert this letter in your next issue. In the course of a very general introduction of chalmoogra oil, in which we have interested ourselves now for more than a year, the difficulty spoken of has never been experienced by us. We have placed the oil in, perhaps, every large hospital in London and in some of these it is now being regularly used ; we have received orders for it from various parts of Scotland and Ireland, and from scores of medical men and chemists in England, who now regard it as part of the ordinary *Materia Medica.* We have also sent the oil to Belgium, Germany, France, North America, the Cape, and Australia

and altogether have distributed some four hundred pounds, not a small quantity in the time, if it be considered that the dose is small, that most of the cases in which it is used are chronic, and that no systematic report on the cases treated has yet appeared. We were pleased to see the unqualified commendation of chalmoogra given by Sir Joseph Fayrer, and Surgeon-Major Balfour. We hold numerous letters from physicians and patients recounting the salutary effect of the oil, but have preferred to file these, pending the more formal and authorised reports. Our experience will show you and others interested in the discussion above referred to, that medical men are not averse to the use of new remedies which come well recommended, and which are brought properly before them. With regard to the supply of it, our sources are so abundant that we do not share the doubt expressed by Surgeon-Major Balfour as to the possibility of obtaining a large quantity of chalmoogra oil. We hold a good stock of the pure oil at the present time, and it is not likely that our arragements will be at all strained, unless a very much larger demand than our experience leads us to anticipate should suddenly arise. In connexion we would refer you to a preliminary paper on the chemistry of chaulmoogra oil by our partner, Mr. John Moss, which appeared in the *Chemist and Druggist*, December, 1878, and to a pamphlet by Mr. R. C. Lepage, late of Calcutta, in which you will find all that has hitherto appeared on chalmoogra oil carefully compiled. We may say that the appearance of this pamphlet was the first important step in our systematic introduction of the oil to medical practice outside of Hindostan.

800, High Holborn, London, 18th March 1879.

CORBYN, STACY, AND CO.

RICE IN JAPAN.

THE Japanese, writes Mr. Mounsey, in a report to the Foreign Office, accord a high antiquity to the origin of the rice plant in their country, their legends stating that it sprang from the body of the daughter of the God of Clay and the Goddess of Fresh Water. They also attribute to this plant the pre-eminent virtue of keeping away evil spirits, and readers of their lore will well remember the first instance of a manifestation of their belief in this virtue. It occurred when the Sun Goddess was induced to leave her dark cave by a variety of cunning devices, but more especially by the curiosity and jealousy excited in her breast by the reflection of her unconscious charms in the fatal mirror; for, being forthwith carried off to a new palace, her abode was at once and henceforth protected by encircling ropes of rice-straw. The wide diffusion of the popular faith in this virtue is evident from the facts that ropes of the same material are to this day stretched across the portals of all Shinto shrines as a protection against evil spirits, and that they are prominently used, with the same intent, in all New Year's Day decorations. Until lately the measure of a man's wealth and income was calculated in rice, and it was almost universally used as the medium for the payment of salaries, wages, and taxes—as the standard of value, in short, in most of the daily transactions of life. Even now the principal item of national revenue, the land-tax, is paid to a considerable extent in rice, one year's experience of the law enforcing money payments having sufficed to show that their continued exaction would be unjust to the farmer. Finally, of all the products of the field, rice is held in the highest honour, and there are, no doubt still many Japanese who are at a loss to imagine how life can be sustained, or the concerns of a nation carried on, without it. It is evident, therefore, that from very remote times rice has been one of the great staples of agricultural produce in Japan. The rice produce of Japan is about double what it was two and a half centuries ago. About a tenth of the entire area of the country is under cultivation, and of this a tenth are rice-lands, a year's crop being estimated at nearly 136,000,000 bushels. Rice, however, is not the staple food of the whole people; large numbers of the lower classes living upon cheaper grains, such as millet, buckwheat, beans, &c., and only indulging in rice from time to time, and in small proportions. The cultivation of rice is more profitably exported to Europe, but it requires a great deal of extra care in storage and ventilation. The Japanese Government has, Mr. Mounsey understands, just ordered a supply of Java seed, and experiments are to be made with it this year. Their alleged reason for this measure is, that Java rice commands the highest price in Europe. They may also hope to obtain a grain which can be shipped on long voyages more easily and surely than the native article. The superiority of Japanese rice in nutritive power is due to the fact that it contains a far larger proportion of fatty matter than any other rice.

Various sorts of spirit and liqueur are also distilled from rice. Mr. Mounsey says:—"There are hard drinkers in Japan, as in most other countries, and, like most Asiatics, the Japanese seem to place less value on the flavour of their liquor than on its intoxicating power. They are certainly fond of carousing, and often given to excessive drinking at festivals and on holidays. This is more especially the case in large towns and in the capital where the results of a laxity of military discipline as regards the sobriety of the soldiers, is too often disagreeably manifest. But there is probably less drunkenness in Japan than in several European countries, and the rice does not there lead to the same fatal consequences. Saké contains such a large proportion of fusel oil that derangements of the stomach cut short the course of intoxication, which, in other countries, and with other liquors, results in *delirium tremens*, and this disease is said to be almost unknown in Japan. On the other hand, some European medical men have attributed the prevalence of paralysis and cognate maladies in certain provinces to the effects of saké, though their opinion is not that of the whole medical profession."

The Japanese Government still receive considerable quantities of rice in payment of taxes, and they are in the habit of purchasing more with their reserve fund for export to Europe, so as to avoid the necessity of remitting coin or bullion in liquidation of the interest on their foreign debt, and for the payment of orders for men-of-war, arms, &c. They are thus almost the only real rice merchants; for few, if any individual Japanese possess sufficient capital at present to enter into large business transactions, and the spirit of association necessary to the formation of companies is still feeble, and has not yet made itself felt in the rice trade. Mr. Mounsey is told, indeed, by European merchants, that it is impossible to obtain a full cargo of rice without applying to the Government. For this reason, and also from uncertainty as to the continuation of the permission to export the grain in question, European mercantile houses cannot embark largely in a trade which must virtually remain a monopoly until the Government ceases to speculate in it, and until it sells its rice at public auction, instead of, as at present, favouring one or two firms with its custom. Rice can, without doubt, be bought in small quantities from native dealers, and it is thus bought by Chinese merchants, but the bulk of the exportable grain belongs to the Government. Mr. Mounsey adds:—"Both political economists and experience condemn, I believe, the practice of Governments becoming traders. In defence of the Japanese Government it may perhaps be argued that a great deal of their rice comes to them in the shape of taxes, and that they are, therefore, justified in making the most of it. But as long as they continue this practice, and can arbitrarily stop the exportation of rice by any but themselves, it is evident that there can be little inducement for the farmer to increase his produce of this grain by enclosing waste lands, and that the rice trade with foreign countries, which might possibly become a source of considerable wealth to the country, cannot be developed to any great extent."—*Globe.*

POPULAR ERRORS REGARDING *PAPYRUS.*

IN Adams' "Roman Antiquities" the Egyptian papyrus plant is described as about ten cubits high, and as having several coats, or skins, one above another like an onion, which coats were peeled off with a pin, in the process of paper making. In Smith's "Dictionary of Greek and Roman Antiquities," it is said that the papyrus tree grows in swamps to the height of ten feet or more, and paper was prepared from the thin coats or pellicles which surround the plant. Liddell & Scott's Greek Lexicon says that "paper was made of the inner bark of the papyrus." And similarly other works of high character, encyclopædias and the like, give a false account of this interesting plant.

Calling attention to these misstatements, in the *Library Journal* Mr. Ezra Abbott, of Harvard University, says: "The papyrus plant (*Cyperus Papyrus* of Linnæus, or *Papyrus antiquorum*, Willd.) belongs to the family of *Cyperaceæ*, or Sedges; it is an endogenous plant, with a triangular stem; and to talk about its 'inner bark,' and 'layers' like the coats of an onion, is a simple absurdity. One might as well speak of 'the inner bark' of a stalk of Indian corn or of a bulrush. The error has originated from ignorance, or forgetfulness of the elements of botany, and the consequent misinterpretation of the passage in Pliny (Hist. Nat., xiii. 11-13, al. 21-27), which is our chief source of information about the ancient manufacture of paper from this plant. One of the words which Pliny uses to describe the very thin strips into which the cellular substance of the stem was sliced in making the paper is *philyræ*, which strictly denotes the inner bark of the linden tree, also employed as a writing material. Hence the papyrus has been conceived of as an exogenous plant, with its outer and inner bark, and has actually been called 'tree.' The botanists of course have not made such a mistake."

Mr. Abbott points out a still more absurd mistake in the English translation of Guhl & Koner's "Life of the Greeks and Romans," which says: "The stalk * * * was cut longitudinally, after which the outer bark was first taken off; the remaining layers of bark, about twenty in number *(philyræ)* were carefully severed, with a pin; and, afterward, the single strips plated crosswise; by means of pressing and permeating the whole, with lime water, the necessary consistency of the material, was obtained." The word mistranslated lime water is *leimoussera* which means glue water.

INDIAN COOLIES IN GUIANA.

We give insertion to the memorial printed below, at the request of the memorialists, who write to us from British Guiana, Gerogetown, Demerara. A copy of the same memorial has been forwarded to the Protectors of Immigrants at Calcutta and Madras. In the letters which accompanies the memorial to those gentlemen, a copy of which has been sent to us, the writers say:—" We have no one to protect us in this colony. The Immigration Agent-General ought to protect us. Instead of his doing so, he, the Immigration Agent-General, is endeavouring to do us more harm than good. He is not our protector, but our oppressor. We therefore solicit your assistance in the matter, and ask you to do all in your power to see redress given us, by your submitting our memorial to the Government of India."

To His Excellency CORNELIUS H. KORTRIGHT, ESQ., C.M.G., Governor and Commander-in-Chief in and over the Colony of British Guiana, Vice-Admiral and Ordinary of the same, &c., &c., &c.

The memorial of the undersigned Indian Immigrants introduced from India to the Colony of British Guiana, and who are residing in the said Colony.

MOST RESPECTFULLY SHEWETH,

1. That your memorialists were engaged in India to come to this colony and work as agricultural labourers, some of them for a period of five years, and others more recently for a longer term of service of ten years, and were informed that at the expiration of these terms, your memorialists and your memorialist's children, whether from India or born in this colony should be provided at the expense of this colony with a free return passage to the port from which they embarked.

2. Some of your memorialists countrymen have been provided, according to their agreements, with such passage to India with their children, whether born in India, or born in the colony.

3. Your memorialists, since 1876, have been deprived of their rights to free return passage, pursuant to the agreements made with them in India, and are compelled by the Immigration Agent-General to remain in this colony, or pay the passage-money of each children born in the colony and infants introduced from India, who were not under indenture on arrival.

4. Your memorialists pray that your Excellency will cause an investigation to be made into this matter and ascertain how and why, and by what authority, our agreements, made in India, are set aside and ignored and made valueless in this colony. Your memorialists beg leave to quote in support of the facts stated in this memorial, the case of a Madras immigrant, Pyneaundy, No. 200, ex *Martin Luther* 1846, who applied for a passage back to India for himself and four children in 1877, and was not allowed a free back passage, but was refused it, except he first paid the passage-money of his children born in the colony. Similar cases have been refused from time to time by the Immigration Agent-General, on account of the inability of the parents to pay the passage-money of their children born in the colony and children born in India, who were not under indenture on their arrival in this country. The clothing money which return immigrants are required to pay is a very large item to a poor and large family, and when in addition to the cost of clothing the passage-money of each member of the family, alleged to be not entitled to free back passage, is required, the parents frequently find it impossible to meet the demand for so much money.

5. Your memorialists think the Government of this colony is bound to keep faith with the immigrants from India, and to provide all the Indian immigrants, desirous of returning to their native land, with a free back passage for themselves and their children, according to the agreements entered into by the agent of this colony and your memorialists in India.

6. Your memorialists feel assured that they have only to bring these facts to the notice of your Excellency and the fullest investigation and inquiry will be made into the nature of their complaints; and justice done in the matter; for which your memorialists will ever pray.

[Here follow 36 names.]

COPROLITES.

A SUFFOLK country clergyman, (the late Rev. J. S. Henslow, deeply imbued with a love for natural history studies, while taking a seaside holiday with his family at Felixstow, had his attention arrested by certain dark-coloured stones which were plentiful in the cliffs of that part of the Suffolk coast, and under a belief (induced by his geological knowledge) that these stones might be the petrified digested food of pre-adamite sharks and sea lizards he sent specimens to London for chemical examination. The result was favourable to his theory. Analysis brought out the important fact that these black pebbles, hitherto looked upon as worth no more than ordinary road gravel or beach shingle, were largely composed of that ingredient so prized by agriculturists, phosphate of lime. The next steps in the history of this discovery and its application, were to collect these phosphatic stones in large quantities, reduce them to powder in stone crushing mills, and then experiment with them as a substitute for guano. The success of these experiments was complete; and it may be said, in a few words, that the natural history knowledge thus accidentally called forth in the course of a seaside ramble has laid the foundation of one of the most important applications of physical science in relation to national wealth that the 19th century has witnessed. Already this discovery has opened out new channels for the employment of human industry and labour. Thousands of the working population in the counties of Suffolk, Herts, and Cambridge are earning good and permanent wages by digging for phosphatic stones, known agriculturally as "Coprolite." Thanks to natural history, science and its happy application in the hands of a Suffolk clergyman, the landed proprietors in that part of the country now know that these long neglected pebbles may be exchanged for gold. They can hardly have received up to this time less than one million pounds sterling as rent or royalty for coprolite digging. And this exchange of stones for gold on the one hand, and on the other the conversion of these stones into bread, may be carried hereafter to an extent which no one can foresee, and reach an importance which, as the population of the world augments, we can hardly in this day appreciate.

Now, contributions of importance to geographical science can rarely be made except under conditions which involve large pecuniary outlay and great personal risk. In astronomy, original observations require costly instruments, and days and nights of continuous and laborious watching. Even in chemistry, little can be done as respects orignal research, whithout a laboratory furnished with appliances of a more or less costly nature. But there are no such difficulties in the path of the naturalist. In whatever part of the world he may be located, and whatever may be his profession or calling, if he have but some knowledge of the rocks, minerals, and fossils which make up the crust of the earth, and of the forms of life which dwell upon the surface of that crust, he can hardly fail to turn that knowledge in some way to account; and while he indulges his own intellectual taste, contribute at the same time to build up the great storehouse of human knowledge. And on this ground, I conceive natural history may very justly rest as one among many reasons that favour its being taught in schools, and so far as first principles are concerned, taking its place with geography and astronomy in that curriculum of study which we all expect our well educated youth of both sexes to pass through.—*Edward Charlesworth, on Natural History as an Element in School Teaching.*

THE EMPIRE UNDER COMPETENT AGRICULTURAL DIRECTION.

NOW that the Supreme Government have seen fit to put a greater amount of responsibility on the local Government, and decentralization is recognised as advisable, we hope that innovations which before were impossible, may, at last, stand some chance of success. It is becoming more and more evident every day that irrigation, as the only panacea to keep up the fertility of the soil, is declining in favour in the minds of those who have the welfare of the country at heart. And while it is probable that the works of the Forest Department will assume dimensions that until recently were never dreamed of, we think their energies should be largely controlled by the agricultural demands of the country, and for this purpose trained agriculturists must unite their counsels with those of the irrigation and forest departments. Large irrigation works have hitherto been constructed solely for their probable value in an engineering point of view, and have resulted in many cases in lamentable failure, because the agricultural side of the question has received no consideration. The ryot has been taken as a unit unworthy of calculation, and his probable wants rather than his actual requirements have been wildly guessed at, and the works undertaken on erroneous assumptions. Nor have the peculiarities of the land received that attention they should. Thousands of acres have been rendered permanently unfertile by our too complete irrigation works when a few rupees forwarded to an analysing chemist would have furnished the Government with facts that would have saved lakhs of rupees. And further, the brains both of the chemist and the agriculturist have been ignored for a rule-of-thumb that nowhere but in India would pass unnoticed. The engineer has rendered square miles of country capable of irrigation, but no pains have been taken to make an analysis of the water, so that we might know its manurial properties and estimate its value as plant food. Water whether it be rich or poor in quality is only water in the eyes of the engineer. Again, it has been pre-supposed that the enormous amount of this fluid the ryot consumes is essential to all growth of the rice-plant, and because it has been the business of no department to prove the contrary we have constructed irrigation works many times as expensive as necessary. To go a step further, we have even adopted the native idea that paddy-cultivation is the perfection of farming, and every drop of water that can be collected in a reservoir for the purpose of irrigation is being put to its best use.

It is only quite recently a few voices have been raised in mild protest against these ideas, but we are glad to say, small as they have been, and few in number, they are now recognised as more than the absurd utterances of idealists. We would even go so far as to say that a suggestion we are about to place before our readers will be read with interest. It has been the custom, as we have already noticed, to look at irrigation only from an engineering point of view, and now there is a chance of this ceasing, and forest conservancy assuming large dimensions. In our opinion, both these departments should

work a large number of their schemes for ameliorating the condition of the country conjointly with an agricultural department—we do not mean the Revenue, Commerce and Agricultural Departments we have, but one composed of men who really do know something of the subject. We should like to see if, for instance, it be determined to improve a collectorate, an agricultural survey, and report submitted in the first instance, exhaustive in its nature, and containing suggestions how a given sum allotted for agricultural improvements could be best distributed. The probabilities of increasing the flow of springs by tree-planting should be dealt with, and also the requirements of the country for cloud-detaining topes, and for trees for a supply of manure and fuel. The forest officer having thus a broad idea to work on, would, in his turn, traverse the country, ascertain the most suitable trees for certain soils, and for local requirements; or, in the event of large areas for reserved tracts, the selection of those varieties which would, in course of years, become of the greatest value to Government. The agriculturist having mapped the country with a view to amelioration by tree-planting, preservation of certain lands for pastures, and the production on the spot of a supply of organic manure for future generations of crops, and the forest officer having his work set out, the engineer might then be in a position to plan and carry out the works of his craft suitably to the condition under which the country might reasonably be assumed to acquire tree-planting by retaining the moisture in the land and enabling the ryot in time to devote his cattle-dung to its legitimate object, manuring his fields, would render the enormous works to resist drought and famine in many cases superfluous, and over large areas instead of the shallow evaporating basins we call, by courtesy, tanks, a curtailed water-supply in the form of small deep tanks and wells might be sufficient.

It is true paddy-cultivation would be curtailed, but which is better—to increase the sanitary condition of the country by the abolition of this, and also enhance the yield and the certainty of crop over the vast area of land devoted to dry cultivation by securing, with the aid of manure, an amount of water in the soil they would tide over any ordinary dry period; or go on as we are doing now, spending enormous sums in rarely remunerative works which are liable, after a time, to become useless by the accumulation of their own silt? Unless the agriculturist is the motive power in a scheme of this sort, we fear the forest officer will forget the agricultural demands of his attention, and devote too much time and money in perfecting forests where they grow best. His work, like the engineer's, is apt to run in a groove, but with agricultural requirements held steadily in view, both can aid in the grand work of ameliorating the condition of the country by cordial co-operation, and achieve results by united action that would otherwise be impossible. We do not wish to absorb the whole time of an engineer in agricultural works; roads must be attended to, and buildings constructed; neither would we wish a forest department wholly to ignore the necessity for directly remunerative forest conservancy. Still, we believe, officers of both departments would do far more general good to the country if they worked in unison and were associated intimately with that at present almost specimen individual—the Indian agricultural officer.—*Madras Times.*

THE SUGAR MAPLE.

[*By Mr. G. Maw, published in the "Gardeners' Chronicle."*]

ACER saccharinum is a much larger tree than the red maple and is at once distinguishable from it by the roundness of the notch between the lobes of the leaves. It is one of the largest trees of the genus, often attaining a diameter of from three to four feet, and out-topping the other deciduous trees, sometimes reaching a height of over 100 feet. For fuel and charcoal its wood is especially valuable; it also produces the well-known bird's eye maple wood used in cabinet work, supposed by Emerson to be a distinct variety of sugar maple, but from information given me in Upper Canada, it seems probable that it is only of mere casual occurrence in individual trees. This species is pre-eminently the source of maple sugar, and was known to the Indians before the settlement of the country by Europeans.

I had the advantage of inspecting on the farm of a Dutch gentleman, near Haysville, a section of the forest in which the maples are tapped, and the collected sap boiled down for sugar, the particulars of which I record.

A very interesting physiological point, connected with the production of maple sugar, is the variability of the flow of the sap dependent on diurnal changes of weather, the whole life-force of the big old trees being apparently ruled by trifling changes of temperature and alternations of heat and frost. Changes of life-action occur which are unappreciable to the eye in the daily development of the spring growth, but which the flow of sap records with precision.

The rising of the sweet sap commences immediately after the first break-up of the long frost from the middle to the end of February, continuing through March and into the early days of April, but varying in different localities and at different seasons. A cold north-west with frosty nights and sunny days in alternation, tends to incite the flow, which is more abundant in the day than the night. It is, however, most sensitive to unfavourable changes, and from a flow of three gallons a day from one tree may almost cease in a few hours, and then gradually recover itself. From this it will be seen that the flow given from day to day is uncertain, and that reliable statistics of produce are difficult to record. A continuous course of favourable weather tends to the largest production, a rising and falling supply reducing the total produce of the season.

The time at which the flow commences varies not only with the season, but with the exposure and elevation of the ground, being earliest in warm and low situations. A thawing night is said to promote its flow, and it ceases during a south wind and at the approach of a storm, and so sensitive are the trees to aspect and climatal variations, that the flow of sap on the south and east sides has been noticed to be earlier than on the north and west sides of the same tree.

There are generally from ten to fifteen good "sap-days" in the sap season, which continues on and off for about six weeks, after which, as the foliage develops, the saccharine matter is reduced, and the sap is said to be "sour," though a restricted flow still continues. Emerson, in his work on the "Trees of Massachussets," referring to Michaux's observations, considers that the product of sugar depends also on the character of the previous summer, and that a season of plentiful rain and sunshine prepares the tree for an abundant harvest of sugar in the succeeding spring. Open winters are thought to cause the sap to be sweetest, and much freezing and thawing to make it most abundant and of the best quality. The sap of isolated trees is richer in sugar than that of those which are massed together in the forest.

In the maple bush at Haysville the produce of sugar was at the rate of 1 lb. to each 6 gallons of sap, and the average may be 1 lb. to 4½ or 5 gallons, but Emerson records instances in which 1 lb. of sugar has been produced from 3 gallons of sap. With reference to the produce of individual trees in a good sap season, an average tree will run as much as 3 gallons of sap in a day, occasionally more, and produce about 4 lbs. of sugar in the season, but Emerson records instances of the production of 10, 20, 33, and 43 lbs. of sugar from single trees. Such weights are, however, altogether exceptional. The highest weight was produced from a draught of 175 gallons of sap from a single tree. The average quantity per tree would be from 12 to 24 gallons in a season.

Young trees under 25 years old are seldom tapped, the smaller trees scarcely paying for the trouble, apart from the debility it produces in the young growing tree. Repeated tapping of the matured trees produces no apparent injury or effect on their vigour. Emerson records instances of trees that have been tapped 40 consecutive years without injury, and it is said that both the quality and quantity of the sap are visibly improved after the first tapping.

The trees are usually tapped at the height of 3 ft. or 4 ft. from the ground, with a ¾-inch auger, to the depth of from 2 inches to 6 inches, into which a perforated plug is driven to lead the sap into the collecting vessels, or a simple notch, 1½ inches deep, is cut with the axe. From one to three taps are inserted in each tree, and these have to be renewed in succeeding years in fresh places, generally alternated on opposite sides of the tree. The sap is evaporated either in iron chaldrons or in shallow boilers, 6 feet long, 2½ feet wide, and about 8 inches deep. Those of copper are preferred to iron, as they are said to yield a whiter sugar.

Care is taken to keep the boilers filled up with fresh additions of sap during evaporation till the syrup attains a sufficient consistency, which is ascertained by its "breaking" or crystallizing when dropped into cold water. The syrup is strained during evaporation, a small quantity of lime or soda added to neutralise any free acids that may be present, and a little white of egg or milk to clear it. After straining and skimming, the syrup is poured into pans or moulds to crystallize, and it may be further clarified by gently boiling in tapering cans with a tap at the bottom, towards which the molasses gravitates, and is drawn off as the crystallized sugar sets.

A considerable proportion of the maple sap product is also preserved as syrup without crystallization, and in this state it is used as sweet sauce and for various culinary purposes.

Maple sugar is made not so much as an article of commerce as for the home use of the producers, and the great bulk being consumed where it is made, it is difficult to arrive at anything like an accurate estimate of the total production. Emerson states that in Massachussets alone between 500,000 and 600,000 lbs. weight of sugar are annually produced from the maple, and he values it at 8 cents. a lb. In 1874 the price rose to from 10 to 22 cents. a lb. In Canada at the beginning of April last, new maple sugar was selling at from 10 to 11 cents. a lb., about the price of the best cane sugar.

The maple sugar production is said to be a growing industry and if the preparation could be centred in well-ordered factories, on the plan of the cheese and butter factories, there is little doubt that carefully-prepared maple sugar would closely compete in price with cane sugar. As it is, with the simple and almost rude appliances for preparation, there is little to choose between the purchase of cane sugar and the cost of producing the local home-made sugar from the sap of the maple.

THE 'TRANSACTIONS' OF THE HIGHLAND SOCIETY.

THIS annual publication has been issued a little later than usual. If there is not as much original matter in the present volume as in some former issues of the 'Transactions,' there is at least no lack of variety. No 'county report' appears this year, but the volume will be none the less useful to members on that account. The short reports of various sorts of experiments on the farm, published this year by the society, are of more service to agriculture than the county reports have ever, or at any rate latterly, been. About one-third of the matter specially prepared for the 'Transactions,' consist of a very interesting and carefully prepared 'Historical Account of the Veterinary Department of the Highland and Agricultural Society.' This exhaustive and well-written description of a highly serviceable department, which began about 1828, and as our readers know is to cease in 1881, was prepared by the society's painstaking and accurate officials, and does credit to the secretary's office.

The place of honour is not unworthily bestowed on the 25 sovereign essay on the 'History of Leases of Lands from the Earliest Times,' written by Mr. M'Culloch, Denbie Mains, Lockerbie. The author's views on leases should not be new to our readers, so that we need not quote extensively from the present report; but we have pleasure in recommending perusal of the clearly written interesting pages before us. Towards the close Mr. M'Culloch advocates greater freedom for the tenants than present leases and customs allow, as also more security for outlay; and in regard to game he says:—

'Game has perhaps more than anything else caused ill-feeling and litigation between landlord and tenant; and as yet no adequate remedy has been afforded by legislation. The Game Bill of 1877 is bad in principle, for it first allows the damage to be done, and a claim for compensation is almost certain to cause annoyance, repeated litigation, and in the end insufficient remuneration. Mutual rights to the game seem the only satisfactory settlement, and, as regards its working, the writer is assured by a landlord of considerable experience, that the discharge of his gamekeepers and trusting his tenants instead, resulted in as good sport and the cementing of better relations between them.'

The familiar and ever-attractive pen of Mr. Hutchison, of Carlowrie, has furnished two useful papers to this volume. They are, as usual, on arboricultural subjects. The one on 'The old and remarkable Spanish Chestnuts in Scotland,' cannot fail to be specially interesting reading to a large number of the society's members.

Mr. John Ainslie, jun., Hillend, near Edinburgh, deserves that medium gold medal awarded to his report on manuring experiments, short as it is. Experiments and reports of this sort should have every encouragement from the society. Mr. Ainslie commenced in 1875 to test carefully the comparative advantages of ploughing in at once dung applied to the stubble in the fall of the year, and leaving it spread on the surface seven or eight weeks. Potatoes formed the first crop after this manuring; and he found that the produce of the part on which the dung lay eight weeks exposed yielded £1 8s. 6d. more per acre than was netted from the part of the field in which the dung was ploughed down within a week. The succeeding crop of wheat showed a balance of 5s. 8d. per acre in favour of leaving dung exposed. On turnip crop that followed, however, there was no visible difference. Mr. Ainslie, as well as his father, is a keen advocate of the system of leaving dung spread on the land for several weeks before it is ploughed in, but he strongly disapproves of letting it 'lie in heaps for weeks.' It should be spread shortly after it is carted to the field.

Professor Tanner, writing on 'Variations in the Composition of Oats,' gives some curious statistics, showing the great variety in the food-producing capabilities of different soils and climates even within the United Kingdom. He also indicates the marked advantage of using strong, well selected seed. Mr. George Grant, Allanichie, Dufftown, received five sovereigns for a concisely written description of the means by which he reclaimed 10 acres of waste land a few years ago. The reclaimed ground is 800 feet above sea level, with a northern exposure, and was formerly mostly under heather. The soil was a mixture of clay and granite, with a clay sub-soil. It was first drained 3 feet deep, 21 yards apart, at a cost of £6 3s. 9d. per imperial acre. The land was then ploughed to a depth of about 7 inches, with a team of three horses, which operation cost about £4 10s. per acre. Two acres were ploughed in the summer of 1869, and the remainder in the following season; 18s. worth of lime per acre was spread on the surface about the time the oats were sown in the spring of 1871, and 2½ cwt. per acre of Peruvian guano were applied. The crop was much better on the two acres first ploughed than on the rest. By the way, 8 bushels of seed were allowed per acre. The first crop yielded, as did the second, about 4 qrs. per imperial acre. After two oat crops a good crop of turnips was grown, and the land was afterwards sown out with an oat crop, and has since been pastured with cattle. From the tabulated statement of income and expenditure, Mr. Grant shows a net profit from his labours during the last eight years of £36 3s. Mr. John Scott, London, contributes a valuable, though short, paper on 'Animal Parasites,' for which he merits and receives a premium of ten sovereigns. Mr. John M. Aitken, Edinburgh, writes on *Hylobius Abietis* or Fir Weevil; while Mr. William Sisling, Nottinghamshire, furnishes an instructive paper on 'The Growth and Cultivation of Willows in Scotland.' The 'Cause of Ringshake in Trees' is intelligently treated of by Mr. Thomas Wilkie, forester, Ardkinglass, Inverary.

By no means the least interesting of useful contribution to the volume is a well-arranged paper by Mr. Thomas Lawson, Sandyford, Kirriemuir, detailing the results of experiments made by him with 'lime and various artificial manures.' To this paper we propose to return at an early date. Last but certainly not least in importance comes Dr. Aitken's report on the Experimental Stations commenced by the Society last May in the Lothians. Owing to the severity of the past winter, and the fact that the long frost had set in before it was expedient to lift the crops upon the several stations, a complete and detailed report of the first season's experiments has had to be withheld. These experiments have been undertaken for the purpose of determining the crop-producing value of the various forms of the most important manures. At each station there are 10 acres under experiment, divided into 40 plots of one rood each. The manures on each plot contain 40lbs. phosphoric acid, 30lbs. potash, and 10lbs. nitrogen. The higher priced dissolved phosphates have been tested in regard as well to their remote as to their immediate action. The difficulties presented by diversity of soil and climate are in the report fully recognised; and the pains which have been taken to avoid hasty conclusions are greatly in favour of the experiments. Speaking of this somewhat perplexing diversity and its effects on field experiments, Dr. Aitken says,—'It would be a great advantage to agriculture, and would immensely enhance the value of the experiments being carried on at these society's stations, if farmers in different parts of the country, who have time and aptitude for that kind of work, would repeat, upon their own lands, any of the sets of experiments described in the accompanying scheme. I would be glad to give to those who would do so any aid in my power.'

The two stations secured for the society's experiments consist of land very different in character and origin, and are described as 'fairly representative of a large part of the arable land of the Lothians.' On Harelaw (Longniddry) the soil is a deep loam, overlying limestone, situated near the sea, exposed on every side, and possessing a fine natural drainage; and is, moreover, one of the earliest districts in Scotland. The Pumpherston station overlies the carboniferous formation, is a thin boulder clay, situated upwards of 300 feet above sea level, and is in a colder, damper, and later district. Acting on the belief that the plots should be as large as possible without being too large, the size chosen has been a quarter of an acre. All the plots are about 400 feet long, with a breadth of 28½ feet, and (as shown by diagrams appended to the report) are so arranged as to give a clear run for the plough of about 800 feet. Experience has served to demonstrate the disadvantage of having a station (all under one crop) so large that it could not be shown in one day. This was found to have been a drawback at both stations. Wet weather at Harelaw caused an interruption of nearly a fortnight in sowing. The varieties of soil, even in one rood, were strikingly exemplified at Pumpherston, and differences in the crop appeared to be traceable to this cause. Indeed, one plot (No. 36) of the Pumpherston station, was so unequal in its soil that it has been deemed advisable to reject it altogether. A chart accompanying the diagrams already mentioned, shows the system of cultivation to be a four years' rotation of turnips, barley, and grass. It deserves to be noted that those crops to which farmyard manure had been applied, suffered greater injury during the severe winter than did the crops which were manured only with artificial manures.

At Pumpherston, the crop was turnips (Fosterton hybrid); and the manure, which had been duly analysed and carefully applied, were protected against wind after the Rothamsted method, by the use of large canvas screens carried alongside the sower, though by this means the outermost drills of some plots received more than their due share of manure,—a circumstance which told on the crop, especially where very light manures were employed. The main facts deduced from both the experiments are briefly summarized as follows:—

'*Phosphate Plots.*—It will be seen from the chart that the first ten plots received each an amount of phosphate containing forty pounds of phosphoric acid. The odd numbers received undissolved phosphate, and the even numbers dissolved phosphate. It was noticed that the plots under dissolved phosphates took the start of the others, and their tops first met in the drills. Thereafter, the differences between the odd and even plots became less and less. When the bulbs were formed the same difference was apparent in them, but it was not so pronounced as one would have been led to expect from the appearance of the leaf. At Harelaw, scarcely any difference could be detected in the size and appearance of the bulbs of these ten plots. Plot 11, however, which received no phosphates, looked very poor, and Plot 12, which received bone-ash alone, even poorer. Plot 5 (bone-dust) and Plot 6 (bone-dust dissolved) were backward at first, but improved considerably towards the end of the season. The plots with mineral phosphates looked quite as well as those with animal phosphates.

'*Nitrogenous Manures.*—No difference was noticeable between Plots 13 (nitrate of soda) and 14 (sulphate of ammonia). The shoddy plot (15) was a very poor one, though it began to improve just at the end of the season. Plot 16 (dried blood) was slow to begin, but it improved very rapidly, and in the end looked better in leaf than the others. Plot 17 (no nitrogen) was a decided failure, especially at Pumpherston, and Plot 18 (nitrate alone) was dark-coloured in the leaf, and came away pretty well at first, but it improved very slowly, and remained very backward.

'*Potassic Manures.*—The sulphate of potash plot looked better than the muriate plot all through the season, but the difference was not great. The

want of potash did not seem to retard the growth so much as one would have expected, considering the large amount of potash which is found in the ash of turnips. Still more unexpected was the appearance of Plot 21, which received sulphate of potash alone. It did not even look so well as the unmanured plots on either of the stations.

'*Guanos* (23-26).—The plots on which these manures were sown were all somewhat backward, especially that with fish guano.

'*Superphosphates* (28-30).—The difference between these plots was trifling. What difference did exist was in favour of Plot 19, which had received the medium amount of soluble phosphate

'*Various Quantities* (31-34).—There was no doubt possible regarding the influence of the manures on these plots. The greater the amount of manure the better seemed the crop. Plot 32, however, was an exception on both stations.

'*Rape Cake and Cotton Cake* (35.)—The half plot with rape cake was decidedly better than the other with cotton cake.

'All these rood plots had the same amount of phosphoric acid, potash, and nitrogen applied to them, except Plots 11 and 12, 17 and 18, 21 and 22, which received a partial manure, and Plot 27, which remained unmanured.

'*Miniature Plots* (36).—Upon the whole, these plots agreed very nearly with the large ones, of which they were duplicates. This, however, applies only to the Harelaw station. The Pumpherston series, as before remarked, is valueless, on account of the inequalities of the soil.'

Before concluding his very interesting report, Dr. Aitken is at pains to point out that, as appearances are often deceptive, too much reliance ought not to be placed on comparisons between the various plots, as that which has the best leaf may not produce the best bulbs, and the large bulbs may not in the end weigh out so well as others. It is also noted that at Harelaw several minor experiments took place. In one of these we are told that :—

'A quantity of seed was divided into three portions, according to their specific gravity. For this purpose the seed was put into a glass cylinder, and water poured upon it. About a fourth rose to the surface, after being well agitated to rid them of air bubbles ; this was taken as light seed. Salt water was then added, till the half of the remaining seed rose to the surface ; this was taken off as medium seed, and the portion at the bottom constituted the heavy seed. The two latter portions were washed to rid them of brine, and all were spread on cloth overnight to dry. Next morning they were sown. The heavy seed sent up a braird of great strength and quantity, the light seed gave a poor sparse braird, and the medium seed was intermediate. They were all thinned at the same time, the light seeds scarcely requiring any thinning. To my great surprise, on inspecting these a fortnight later, the light seed drills were the best, the heavy ones the worst, and the others intermediate, and this position was maintained during all the growing season. The reason of this was not difficult to find. Of the heavy seed nearly every seed grew, and of course a great struggle took place for the food contained in the soil, and they were not able to make such good root as the few living seeds among the light portion, and what roots they did make were much disturbed in thinning out their closely-packed neighbours. This experiment shows the evil of thick sowing. It is to be noted, however, that there was no appearance of turnip fly. Had that pest appeared, there would probably have been no crop at all from the light seed.

'Samples of 40 carefully selected turnips were taken from each of the plots at Pumpherston before the frost set in—that is to say, about four months ago—and a large proportion of these have been analyzed, and afford results which will be interesting and instructive when taken in connection with the full report of the cropping at both stations ; but to make any observations on them in their present state would be premature, and might even be misleading.—*N. B. Agriculturist.*

THE GARDEN.

EVERY resident in the country, with an eye for plants, must be familiar with the circular black spots on leaves of the sycamore and maple. According to M. Max Cornu, as quoted in the last number of *Grevillea*, these spots are the work of a parasitic fungus sometimes called *Xyloma acerinum*. This Xyloma is, however, only a transitory form of the fungus, for when the leaves fall to the ground in the autumn a new growth appears in these spots, the plant produces asci, and becomes *Rhytisma acerinum*. The parasite is annual in its duration, and is altogether confined to the deciduous foliaceous organs ; it is only fully developed on the organ when they are in a young state. In order to destroy the fungus it is enough to remove all the spotted leaves which fall in autumn.—*Gardener's Chronicle.*

THE VICTORIA REGIA.

A MOST interesting experiment in acclimatisation has lately been successfully carried out by Mr. Sowerby, the Secretary to the Royal Botanic Society, who conceived the idea of transplanting to equatorial Africa one of the most remarkable specimens of the flora of the American continent, viz., the gigantic water lily, the largest and most beautiful of known water plants, named, in honour of the Queen, Victoria Regia. This magnificent plant was discovered about forty years ago by Sir R. Schomburgh, whose explorations in Guiana and the neighbouring countries in the northern portions of South America, threw so much light on these then little known lands. It grows abundantly in the warm waters of the Amazon, where it attains a size, the mere mention of which would have sufficed to place it at once in the category of "travellers' wonders," had not the scientific and energetic explorer been fortunate enough to bring home living proofs of his assertions. Splendid plants have been grown from seeds at the Royal Botanic Gardens at Kew, and elsewhere, though, of course, not equaling the lily in its native waters, were its great round leaves cover an enormous area. Having been reproduced under artificial heat, in warm water—and once even in the open air—in this country, the flower has travelled to Central Africa. Seeds grown in London were first sent to Zanzibar, where they produced plants which now adorn the gardens of Seyyid Barghash, and more lately they have been carried to Lake Nyanza, where it is confidently anticipated that they will find a congenial home. Though some 6,000 miles distant from the Amazon, this lake, is in the same latitude, and the whole system of lakes and rivers in Central Africa may eventually find a new ornament in a water plant peculiar to the New World, having first halted on its migration, so to speak, in London. Some seeds have also been taken out to China by the late Chinese Ambassador, and as Mr. Sowerby's experiments have proved the best way of transporting the seeds, this plant will no doubt, as he says, soon be "naturalised in the remotest corners of the globe." The seeds resembled in shape and size black pigeon peas, and if kept in water in the light they will remain alive a year or more without sprouting. If placed, however, in darkness and at a moderate temperature they begin to grow, so that the task of safely carrying them throughout a long and tedious journey like that to China or Lake Nyanza is one requiring no slight attention.—*Globe.*

PRACTICAL HINTS ON FLOWER GARDENING IN MADRAS.

A GARDEN to be a pleasure should be always neat and tidy. Nothing looks more untidy than decaying leaves and flowers, and, as a matter of fact, nothing tends to keep plants longer in flower, than picking off all old flowers and not allowing plants to bear seed. If any seeds are wanted they should be grown on one or two plants, selected and planted out of the way somewhere. It is seed-bearing which wears out plants and makes them look dried up and unsightly. But besides this a great thing in a garden is to have a constant succession of flowering plants. If a plant gets withered and past its work ; or if the season for one description of flowering plant is over, a great matter is to have another kind ready to put in its place. One of the great beauties of a good English garden is the constant succession of flowers. First, in the spring, bulbous flowers, crocus, tulip, hyacinth and the like. On some warm morning in May the garden appears transformed. The bulbs are all gone and the beds, as if by magic, in a night are filled with flowering geraniums, foliage plants and midsummer flowers. Again, later in August, the same transformation takes place, and dahlias, chrysanthanums and the "last rose of summer" suddenly bloom in the parterre. This change is managed by having the plants ready in pots. A great deal can be done in India in the same way, if not by completely changing the bed, yet at all events in freshening up and renewing plants, where they have died or become old and withered. Very fair flower pots are made at Madras, but they are not so good as those in some parts of the Mofussil. One reason flower pots often fail in Madras is, that garden owners buy them in the wet season, and even order them at that period. The consequence is they are burnt without being thoroughly dry, and are easily made rotten by constant watering. A well-burnt pot will last a long time. Whenever and wherever they are obtained, care should be taken not to buy pots with too small a circumference at the bottom. Some flower pots in Madras have been lately made which are as large and round below as above. This is wasteful of soil and wasteful of space. The surface roots of plants want more room than those below. Besides, if this plan was adopted for small pots, there would be a difficulty in getting the plants out with the earth attached to them when moving them. It is, of course, impossible to say what flower-pots a person may require for his garden, but for the purpose of keeping a stock of flowering plants ready to fill up vacancies, the best size are pots about six inches in diameter at the top or mouth. Lateral drain holes are better than holes at the bottom. When flower pots drain in the latter method the roots of all sorts of plants find their way through and get into the ground under the pot. It is well, before potting commences, to have two heaps of broken bricks or tiles ready. One heap containing pieces about as large as small limes—the other composed of smaller pieces about the size of filberts. Bamboo sieves can be made by any mat-makers for about two annas each with meshes of any size fancied. After the bricks, of tiles, or whatever is used for drainage, are broken up, two heaps of uniform sized pieces can be easily obtained by sifting the broken stuff, first through the large sieve, and then through the smaller one. Supposing then the pots to be ready and the broken pieces of bricks and some compost and, silver

[illegible] as before mentioned, at hand. Let us consider how to proceed to transplant into pots a lot of balsam seedlings; it is assumed the balsam seed has been sown some time before in a large pot, and that the young plants have got about four leaves. Commence by filling a dozen flower pots. First, put into the bottom of each pot a handful of broken bricks, from the large heap, than a handful from the smaller heap —care being taken to put in enough to cover the drainage holes, if they are at the side. Give the flower pot a shake, so as to settle the broken pieces together. Then, having mixed the sand and mould, fill each pot with the mixture to the brim. After doing this, give the pot another shake. Just as tea dealers may be seen shaking the tea into papers to make it settle; this will bring the soil a little below the surface of the flower pot, as it should be, to allow of proper watering. After the flower pots are all thus filled, take a flat piece of bamboo which has been cut into the shape of a table knife blade, and with it carefully take up and put into each pot, one or more of the flower seedlings from the pot in which they are growing; keep these thus transplanted, in a cool place out of the sun, and out of any draft and without much water for a few days. By this plan a constant supply of young plants of every kind may be kept without much trouble, and at little expense. All sorts of young seedlings may be treated in this manner, and almost all kinds of seeds may be sown, at all seasons to procure seedlings. If those seedlings were put at once out into a bed, they would not resist the heat of the present season for a day, and will not do half as well at any season as they would do if brought forward, to about a dozen leaves in pots. The natives of India are very quick at learning all the manual part of gardening. They will learn to pot many dozen seedlings in a morning, and, what is better, will learn to move plants either from one pot to a large one, or into a bed without breaking the ball formed in the pot or throwing the plants back a day. Native gardeners may be taught everything, but judgment. The same plan of potting plants should be adopted in moving larger plants. Sometimes it is as well to have two men. If the plant is a large one, let one man put the palms of his hands on the soil of the pot, one palm on each side of the stem of the plants. The other man should then turn the plant over on to the palms of the hands of the first man and lift the pot off. The plant will then remain, but upside down, in the first man's hands, the ball of earth that has come out of the pot, being probably full of roots, and crowned on the top with the brick rubbish that had been put in the first instance into the flower pot, to drain it. Pick this brick rubbish off, and then slowly turn the plant round into the hand of the man who removed the pot, who should put it into the fresh pot destined for it, or into the bed as desired. By this means the plants never stop growing. They will always be healthy and will be strong to resist the attacks of insects and the change in the weather. After potting any plants keep them in complete shade for twenty-four hours, then put them out where they can get the morning sun. And in a day or two, if they are hardy plants, and the season is favourable, put them in the open, so as to get hardened. Do not give much water to potted seedlings, until they seem to be growing well. Then, and especially if in the opening, they should be watered freely every evening, as plants in pots get very dry in a short time. Sometimes large shrubs in pots are as well if not moved. Their roots have got through the bottoms of the pot into the grounds, and it would throw them back very much to move them. They will be much benefitted, if all the soil round the edge of the pot they are growing in, is removed. Cut away as deeply as you can a little ditch of the width of an ordinary garden trowel. As a rule, the soil in the pot will be so full of fine roots, that there will be no difficulty in cutting as narrow a ditch all round the inside of the pot as you wish. The fine roots will keep up the soil. Throw away all this earth that you have dug out. It will be completely exhausted of all nutritious qualities for the plants and in place of it put in a mixture of the best stuff you can afford, bone dust, if you have it, and compost mixed or else compost alone or even common red earth. Anything to give the roots a change of food that they may send some sap to the branches and leaves. Large crotons and shrubs treated thus twice a year will well repay the trouble.—*Madras Times.*

ECONOMIC USES OF THE PLANTAIN.

At a meeting of the Paris Academy of Sciences, on January 7th, Messrs. V. Marcans and A. Muntz briefly drew attention to the composition of the plantain and some experiments as to the utilisation of its fruit. It is strange, considering the abundance and cheapness of the plantain, which in many localities is suffered to perish from its abundance, how little has been as yet done commercially with it.

We have repeatedly drawn attention to its various products, among others in our work on "The Commercial Products of the Vegetable Kingdom," in different volumes of *The Technologist*, a in and recent work on "Tropical Agriculture." It may, however, be well to bring together some few of these published details, in order to amplify the very brief note of Messrs. Marcans and Muntz, which we will give first. These gentlemen state:—"The fruit of the plantain, or banana, is one of the food products most widely distributed in equatorial regions. Boussingault observes in his "Rural Economy," that the plantain forms the common nourishment of the people in warm regions. Between the tropics its culture is as important as that of the cereals and tuberous food plants in the temperate zone.

"In Venezuela, the plantation continues to spread more and more widely, and the population can consume but a very small portion of the fruit produced; hence attempts have been made to utilise some of the products for export. The last Paris Exhibition showed some steps taken in this direction, among others, plantain meal, obtained by drying and pulverising the fruit, gathered before fully ripe, and spirit obtained by distilling the ripe fruit after it had commenced alcoholic fermentation.

"This plantain spirit, after the first distillation, has a pleasant odour and an agreeable taste, marking 53° of the alcoholometer. The fruit, as it is received in bunches at Paris, perfectly ripe, and in a good state of preservation, will undergo the alcoholic fermentation if left to itself.

"The following is an analysis of the plantain as grown in Venezuela:—

"100 parts of fruit consist of 40 of skin or peel, and 60 of pulp. The skin contains 14·7 per cent. of dry matter, and 1·6 of interverted sugar; 100 parts of the pulp contain 73·8 of water, besides 8·5 of cane sugar, 6·4 of interverted sugar, and the remainder is made up of starch and other substances.

"The proportion of sugar is considerable in the ripe fruit, although the cane sugar cannot be profitably extracted, it is considered that it might be utilised for the production of spirit.

"At the time of Boussingault's travel's, the price of plantains was but a franc the 100 kilogrammes, and this weight would yield 9 litres of alcohol of 96o strength. The cost in many localities is now merely the trouble of collecting. Hence plantain spirit may possibly compete with that made from the refuses of the sugar cane."

Humboldt calculated that the same extent of ground, when cultivated with the plantain, will support a far greater number of people than when planted with wheat. The yield has, however, been found to differ with the mean temperature of the place. Boussingault has given the following as the produce per imperial acre of the raw fruit in three places:

	Temp.		Produce per acre. Tons.		Dry Food per acre. Tons.
Warm regions ...	81½°	...	72	...	19½
At Canca ...	78½°	...	59	...	16
At the Hague ...	71½°	...	25	...	6½

Professor Johnston is the authority for the last column, or that of dry food per acre, as he had, from his analysis, obtained 27 per cent. of nutritive matter from the banana.

The extraordinary accounts which have from time to time been published with regard to what a plantain walk was thought to yield, have failed to attract capital to this branch of agriculture. These calculations were not always extravagant, some have been sober enough, and yet they showed considerable returns. Several tons of plantain flour, besides one and a-half tons of fibre, can be obtained per acre, and the outlay for tillage and machinery is small.

The plantain is gathered at three different stages. At a fourth part of its maturity it is rather milky and contains much starch. If it is roasted in ashes or boiled in water it forms a very nourishing food, capable of being substituted for bread. When cut at three-fourths of its growth, it is less nourishing, but contains more sugar; in this state it is eaten as an accompaniment to meat. Lastly when the fruit is fully ripe, all the starch is changed into gum or sugar; it then develops an acid principle; it is eaten either raw or in the form of fritters. The banana, the other edible species, which is only eaten when perfectly ripe, is rather a fruit than a nutritive food; it is soft, full of sugar, melting, and possesses a powerful perfume, and forms a principal dish for dessert in tropical regions. In those countries they cut them while still green, and hang the bunches in their houses to ripen.

To hasten their ripening in China they are covered with rice or even with lime. The Chinese also eat the flowers of the plant pickled in vinegar. The plantain, when plucked ripe, keeps fresh for about a week; at the end of that time it becomes yellowish and more sugary; in twelve or fifteen days it begins to decompose and ferment. In South and Central America there are two methods of preserving the plantain for food; the first, used when the fruit is green, produces plantain meal, the other, when the fruit is completely ripe, produces the *platano pasado* of the Mexicans or the *platano curado* of New Granada.

Mr. W. W. Anderson, in an article in my journal, *The Technologist*, in 1867, thus spoke of the flour of the plantain. "This is well known in many parts of the West Indies under the name of 'Conquintay,' and is highly esteemed and extensively used as a food for invalids and children. It is decidedly superior in these respects to arrowroot, in consequence of its nourishing and strengthening qualities. It may also be stated that it is curative of diarrhœa and similar bowel complaints in consequence of the tannin which it contains. It is hardly known in Europe, where, however, we believe it would be greatly prized, and would supersede the patent groats, patent pearl barley and similar preparations. The plantain for flour must be cut, not only before it is ripe, but a little before it is what is called 'full.' It should not, in any of the processes to which it is to be subject, come in contact with iron or steel, which instantly imparts to it an inky black colour.

"It must be sliced with nickel or silver plate, or even bone or hard wood knives, and dried. The thin slices should be baked in an oven for eight hours, or dried in the sun for a couple of days, and then pounded in a wooden mill or mortar and cooked in a tinned or enamelled vessel. There is a pleasant soft fulness in the taste of cake or pottage of the plantain flour, which will always recommend it, in whichever of the forms above stated it is used except baking it into bread. Plantains from their bulk, cannot be transported from interior places in the green state, but

when made into flour the value will bear the charges of transportation, aye of exportation too.

"The starch drawn off from the green-grated plantain appeared to me unusually thick and clammy. I wish that some one better acquainted with the qualities on which the commercial value of the article to the manufacturers depends, would examine and report on it.

"The residue after the starch is separated, what I may call plantain tapioca, is a pink-coloured substance, which crumbles easily, and when cooked (always avoiding iron vessels) as is done with arrowroot and tapioca, and seasoned with sugar, it forms, with milk, a pleasant food of a delicate and agreeable flavour. But, besides being a good strengthening food for children and persons of sedentary habits, from its lightness and easiness of digestion, it would, I think, be a substantial food for labourers, especially Europeans.

"Plantain meal will no doubt acquire great importance in foreign countries when its nutritous properties, 5 per cent. of nitrogenous matter, become more generally known. The best way of procuring the farina fresh would be to import into Europe the dried slices and grind them."

This is a speculation which could not fail to be successful in the colonies seeing that a bunch of plantains, stripped of the skins, give at the least 50 per cent. of pulp; and the fresh pulp furnishes 40 per cent. of dry farina. The yield is usually about 8lbs. per bunch of a mean weight of 25lbs. An acre of plantains would give on the average 450 bunches, yielding 1,350 lbs. of meal. There is another method employed in South America, but it is defective in a great many points as compared with the dried slices. They grate the fruits, having first peeled them, squeeze the moisture out in a press and bake them, like manioc, in an oven, and by this means obtain a coarse kind of flour. But the nutritive property of this is inferior to that prepared from the dried slices, for no doubt the pressure which extracts the moisture, expels also the soluble albumen and other nutritious qualities.

The best method of preserving the banana very closely resembles that commonly used in the preparation of dried fruits, such as figs, prunes and raisins. The time chosen is when the fruit is quite ripe and its skin has become of a yellow colour, shaded with black. In the hot regions of Mexico the banana are dried simply by exposure to the atmosphere. They are laid in the sun in bundles, and when they begin to wrinkle they are peeled, the skin if left on causing a disagreeable flavour. They are kept for some time, until an efflorescence of sugar appears on their surface, as on dried figs and prunes. They are then pressed into masses of about 25 lbs. each and wrapped with leaves of the plant. There are three distinct ways in which the ripe banana may be dried :—

Firstly exposing the fruit to an atmosphere of sulphuric acid gas before the desiccation is begun. Secondly, boiling rapidly very ripe fruit in water which contains sulphate of lime. Thirdly, by boiling it in syrup. By either of these the albumen and casein of the fruit coagulates and the tendency of the banana to decay and ferment is stopped at a period favourable for desiccation. Experience shows that the second method is the best to employ; in moist climates, without this precaution, the fruit instead of drying becomes damp. To expose the fruit to the sun's rays after boiling, trays of bamboo, as in Mexico, or of anything which permits the free action of the air and light on the fruits, may be used. If rain falls they are dried in a furnace, which must be left open, otherwise the bananas bake instead of drying. The heat also must be moderate.

Probably Alden's fruit-dryers, a system adopted in the United States, might be found useful. Bananas, when pressed and packed in boxes, will keep perfectly good for any number of years. The fruit thus prepared is a very good article of food, resembling figs or dates, and its abundance and easy preparation would render it a cheap one. Many spirituous drinks, as well as vinegar, are made from the banana. Banana wine is obtained in Cayenne by pressing the fruit through a sieve and then making it into small cakes, which are dried in the sun or on hot cinders. When wanted for use they are dissolved in water. Another way is to boil the fruit, and passing them through a sieve to separate the skin; they are melted and bruised in the same water. From bananas soaked in brandy a liqueur is prepared which preserves the taste of the fruit; other liqueurs are also obtained by a process of fermentation.

FORESTRY.

THE *Builder* states that M. Lostal, a French railway contractor, recommends quicklime as a preservative for timber. He puts the sleepers into pits, and covers them with quicklime which is slowly slaked with water. Timber for mines must be left for eight days before it is completely impregnated. It becomes extremely hard and tough, and is said never to rot. Beech wood prepared in the same manner has been used in several ironworks for hammers and other tools, and is reputed to be as hard as iron, without losing the elasticity peculiar to it. According to the *Kurse Berichte*, lime slaked in a solution of chloride of calcium is used at Strasburg as a fireproof and weatherproof coating for wood.

THE Government of the United States seems to be arousing itself as to the necessity of putting some check upon the reckless destruction of timber which is going on all over their vast territory, wherever a settler or lumberman sets his foot. In his annual report to the President, Mr. Schurz, the Secretary of the Interior, devotes considerable space to the necessity of taking steps to insure the preservation of the forests. He expresses his opinion that the disastrous consequences which always follow the destruction of timber in a country will inevitably come upon the people of the United States in a comparatively short time, on account of the rapidity with which the timber growth of the country is being swept away, unless legislation steps in to arrest this indiscriminate destruction. He strongly renews his recommendation for the passing of a Bill, already introduced in Congress at his suggestion, which enacts that all timber lands, which are chiefly valuable for the timber upon them, shall be withdrawn from sale or any other alienation under existing laws, and shall continue to be held by the Government with a view to prevent the injudicious destruction of the timber, and to protect the growth of young trees.

WE learn from a recent Forest Report that the maple is assuming a very important place in the forests near Darjeeling, yielding as it does a very fair firewood, and being raised with the least amount of trouble. It will form in future the main stand-by in reproductive measures, the more valuable trees being planted here and there among the maple woods. There are now five acres under Spanish chestnut, but the results are not satisfactory, and it is not intended to send more seed of this kind to Bengal.

SOME interesting statistics relating to the area of forest land in France have been published in connection with the Agricultural Budget of that country, recently under discussion in the Chambers. From these it appears that at the present time France possesses 9,185,310 hectares of forest, representing a sixth part of the whole extent of territory. Of these 967,120 hectares belong to the State, 2,058,729 hectares to communes and departments, and 32,059 to public bodies or establishments. In former times the State owned a far larger extent of forest, which underwent a constant diminution between 1791 and 1872. From 1814 to 1830, under the Restoration, 168,826 hectares were alienated; from 1830 to 1848 the Monarchy of July got rid of a further 118,166 hectares; and finally, under the Second Empire, 71,930 hectares were lost between 1852 and 1870. The transference of Alsace and Lorraine to German hands brought with it a further diminution to the extent of 97,025 hectares, and the restitution of the property of the Orleans family involved a last surrender of 430,614 hectares more. Under the terms of the law passed in 1874, the State has bought since that date 10,000 hectares of mountain forest lands, but the produce of these and former possessions still retained is altogether insufficient to supply the demands of the home consumption. Of the 967,120 hectares now belonging to the State 130,929 are returned as absolutely unproductive. The remainder yield an annual income of 3,678,000 francs.—*Country Gentleman's Magazine.*

MANY of our readers are familiar with the large cabbage-like leaves of the robust *C. succirubra*. The coolies use them as substitutes for plates. We have seen a good many big *succirubra* leaves, but we think the specimen which reached us by post from Mr. Edward Thwaites of Hakgala Gardens is the largest yet. To the eye it looks almost round, and when measured it gave 16 inches from junction with stem to point and 12½ inches across the middle for breadth. As the breadth diminishes but slightly towards the point, we have here a superficies of nearly 200 inches, or over 1 square foot! In length, however, the first leaf of Liberian coffee sent to us by Mr. Charles Strachan, of Messrs. Carey, Strachan & Co., left this big leaf far behind,—the measurement for length being 21 inches, or only 3 inches short of 2 feet!—Mr. Thwaites tells us that the leaf of *C. succirubra* now forwarded by him was taken from a sucker of a tree cut down or coppiced last year.—*Ceylon Observer.*

As a proof of the humidity given to the atmosphere by trees, experiments show that the "Washington Elm," at Cambridge, Mass, with its 200,000 square feet of leaf surface, transpires seven and three quarter tons of watery vapour in twelve diurnal hours of clear weather. From this it is inferred that a grove, consisting of 500 trees, each with a leaf surface equal to that of the elm mentioned, would return to the atmosphere 3,875 tons of aqueous vapour in twelve hours.
